## SOLUTIONS TO PROBLEMS, CHAPTER 1

## 1. 1 Fog formation

1. The saturation vapor pressure of water at 293 K is $P_{H 2 O, S A T}=23 \mathrm{hPa}$. At sunset the air is at $50 \%$ relative humidity, therefore $P_{H 2 O}=11.5 \mathrm{hPa}$. The dew point corresponding to this water vapor pressure is 282 K . The air must cool to 282 K in order for fog to form.
2. From the phase diagram we find that the stable phase of water is liquid. The fact that the atmosphere contains water vapor simply means that it is not in equilibrium. Under these conditions water will condense to produce a liquid phase, and $P_{\mathrm{H} 2 \mathrm{O}}$ wil decrease until the gas-liquid equilibrium line is reached. Under isothermal conditions $\left(20^{\circ} \mathrm{C}\right)$ equilibrium will be reached for $P_{H 2 O}, S A T=23 \mathrm{hPa}$, so that $77 \%$ of the water vapor initially present will have condensed.

## 1. 2 Phase of water in a cloud

The saturation vapor pressure at 273 K is $P_{\mathrm{H} 2 \mathrm{O}, S A T}=6 \mathrm{hPa}$. The corresponding mass concentration $\rho_{\mathrm{H} 2 \mathrm{O}}$ is

$$
\rho_{\mathrm{H} 2 \mathrm{O}}=\frac{M_{H 2 O^{P}} \mathrm{H} 2 \mathrm{O}}{R T}=\frac{18 \times 10^{-3} \cdot 6 \times 10^{2}}{8.31 \cdot 273}=4.8 \times 10^{-3} \mathrm{~kg} \mathrm{~m}^{-3}=4.8 \mathrm{~g} \mathrm{~m}^{-3}
$$

Considering that cloud liquid water contents are in the range $0.1-1 \mathrm{~g} \mathrm{~m}^{-3}$, we conclude that most of the water in a cloud is present as vapor.

## 1. 3 The ozone column

1. At the peak of the ozone layer, $n_{\mathrm{O} 3}=5 \times 10^{12}$ molecules $\mathrm{cm}^{-3}$. The density of air at that altitude is

$$
n_{a}=\frac{A_{v} P}{R T}=\frac{6.022 \times 10^{23} \cdot 35 \times 10^{2}}{8.31 \cdot 220}=1.2 \times 10^{24}{ }_{\text {molecules } \mathrm{m}^{-3}}=1.2 \times 10^{18}{\text { molecules } \mathrm{cm}^{-3}}^{-3}
$$

and the corresponding $\mathrm{O}_{3}$ mixing ratio is $\mathrm{C}_{\mathrm{O} 3}=n_{\mathrm{O} 3} / n_{a}=4.2 \mathrm{ppmv}=4200 \mathrm{ppbv}$. This is fify times the $\mathrm{O}_{3}$ air quality standard for surface air!
2. In surface air, $n_{\mathrm{O} 3}=1 \times 10^{12}$ molecules $\mathrm{cm}^{-3}$. The density of air at that altitude is

$$
n_{a}=\frac{A_{v} P}{R T}=\frac{6.022 \times 10^{23} \cdot 1000 \times 10^{2}}{8.31 \cdot 300}=2.4 \times 10^{25} \text { molecules } \mathrm{m}^{-3}=2.4 \times 10^{19} \text { molecules } \mathrm{cm}^{-3}
$$

and the corresponding $\mathrm{O}_{3}$ mixing ratio is $\mathrm{C}_{\mathrm{O} 3}=n_{\mathrm{O} 3} / n_{a}=42 \mathrm{ppbv}$, which is in compliance with the $\mathrm{O}_{3}$ air quality standard. The relative decrease of $\mathrm{C}_{\mathrm{O} 3}$ from 25 to 0 km is much larger than the relative decrease of $n_{\mathrm{O} 3}$ because of the change in atmospheric pressure:

$$
\frac{C_{O 3}\left(z_{2}\right)}{C_{O 3}\left(z_{1}\right)}=\frac{n_{O 3}\left(z_{2}\right)}{n_{O 3}\left(z_{1}\right)} \cdot \frac{n_{a}\left(z_{1}\right)}{n_{a}\left(z_{2}\right)}=\frac{n_{O 3}\left(z_{2}\right)}{n_{O 3}\left(z_{1}\right)} \cdot \frac{P\left(z_{1}\right) T\left(z_{2}\right)}{P\left(z_{2}\right) T\left(z_{1}\right)}=0.048 \frac{n_{O 3}\left(z_{2}\right)}{n_{O 3}\left(z_{1}\right)} \text { between } 0 \text { and } 25 \mathrm{~km}
$$

3. The $\mathrm{O}_{3}$ column $C$ is the total number of $\mathrm{O}_{3}$ molecules per unit area of Earth's surface:

$$
C=\int_{0}^{\infty} n_{O 3} d z
$$

For the triangular function proposed here as an approximation to the $\mathrm{O}_{3}$ profile, the integral is simply the area of the triangle ( $1 / 2 \times$ base $x$ height). We carry out the numerical calculation in SI units:

$$
\frac{1}{2} \times(30 \mathrm{~km}) \times\left(5 \times 10^{12} \text { molecules } \mathrm{cm}^{-3}\right)=0.5 \cdot 30 \times 10^{3} \cdot 5 \times 10^{18}=7.5 \times 10^{22} \text { molecules }^{-2}
$$

4. Consider the above $\mathrm{O}_{3}$ column brought to sea level as a layer of unit horizontal area $A$ and vertical thickness $h$ (volume $V=A h$ ) at $P=1.013 \times 10^{5} \mathrm{~Pa}, T=273 \mathrm{~K}$. The column contains $7.5 \times 10^{22}$ molecules, corresponding to $N=7.5 \times 10^{22} / 6.022 \times 10^{23}=0.125$ moles. Apply the ideal gas law to obtain $h$ :

$$
P V=N R T \Rightarrow h=\frac{N R T}{P A}=\frac{0.125 \cdot 8.31 \cdot 273}{1.013 \times 10^{5} \cdot 1}=2.8 \times 10^{-3} \mathrm{~m}=2.8 \mathrm{~mm}
$$

## SOLUTIONS TO PROBLEMS, CHAPTER 2

## 2. 1 Scale height of the Martian atmosphere

$$
H=\frac{R T}{M_{a} g}=\frac{8.31 \cdot 220}{44 \times 10^{-3} \cdot 3.7}=11.2 \mathrm{~km}
$$

which is larger than the scale height of the Earth's atmosphere. The atmosphere of Mars extends deeper than that of the Earth because of the smaller size of Mars and hence its weaker gravitational pull on its atmosphere.

## 2. 2 Scale height and atmospheric mass

1. The mass $d m$ of the species in an elementary slab of atmosphere of unit area and vertical thickness $d z$ is $d m=\rho(z) d z$. We integrate over the depth of the atmosphere and over the area $A$ of the Earth:

$$
\begin{equation*}
m=A \int_{0}^{\infty} \rho(z) d z=A \int_{0}^{\infty} \rho(0) e^{-\frac{z}{h}} d z=-\left.A \rho(0) h e^{-\frac{z}{h}}\right|_{0} ^{\infty}=A \rho(0) h \tag{1}
\end{equation*}
$$

2.1 From the ideal gas law:

$$
\rho_{a}=\frac{M_{a} P}{R T}
$$

where $M_{a}=0.029 \mathrm{~kg} / \mathrm{mol} ; T=288 \mathrm{~K}$; and $P=9.84 \times 10^{4} \mathrm{~Pa}$. We use SI units for all quantities to avoid unit conversion mistakes. In this manner we obtain

$$
\rho_{a}=\rho(0)=\frac{\left(0.029 \frac{\mathrm{~kg}}{\mathrm{~mol}}\right)\left(9.84 \times 10^{4} \mathrm{~Pa}\right)}{\left(8.31 \frac{\mathrm{~J}}{\mathrm{~mol} \cdot \mathrm{~K}}\right)(288 \mathrm{~K})}=1.19 \frac{\mathrm{~kg}}{\mathrm{~m}^{3}}
$$

2.2 We substitute in equation (1) $A=4 \pi R^{2}=5.1 \times 10^{14} \mathrm{~m}^{2}$, where $R=6400 \mathrm{~km}$ is the radius of the Earth; $\rho(0)$ $=1.19 \mathrm{~kg} \mathrm{~m}^{-3}$; and the atmospheric scale height is $h=7.4 \times 10^{3} \mathrm{~m}$. The resulting mass of the atmosphere is $m=4.4 \times 10^{18} \mathrm{~kg}$, somewhat lower than the value of $5.2 \times 10^{18} \mathrm{~kg}$ derived in the text. The reason for the difference lies in the assumption $\rho \sim P$ made when applying the barometric law to air density. In fact $\rho \sim$ $P / T$ (ideal gas law); as $z$ increases and $T$ decreases, $\rho(z)$ deviates upward from the value $\rho(0) \exp (-z / h)$ predicted from the barometric law and hence equation (1) underestimates $m$.
3.1 We apply equation (1) to sea salt, taking into consideration that sea salt is emitted over only $70 \%$ of the globe.

$$
m_{S S}=0.70 A \rho_{S S}(0) h_{S S}=(0.70)\left(5.1 \times 10^{14} \mathrm{~m}^{2}\right)\left(10 \times 10^{-9} \frac{\mathrm{~kg}}{\mathrm{~m}^{3}}\right)(500 \mathrm{~m})=1.8 \times 10^{9} \mathrm{~kg}
$$

## SOLUTIONS TO PROBLEMS, CHAPTER 3

## 3. 1 Ventilation of pollution from the United States

1. Let $W$ and $h$ represent the width and height of the box respectively. The volume of the box is $L W h$. In one unit time a volume $U W h$ of air flows out of the box. The residence time of air in the box is therefore:

$$
\tau_{o u t}=\frac{L W h}{U W h}=\frac{L}{U}=\frac{5 \times 10^{6}}{10}=5 \times 10^{5} \mathrm{~s}=5.8 \text { days }
$$

2. Let $m$ represent the mass of the pollutant in the United States box. The pollutant is removed by chemical loss (time constant $\tau_{\text {chem }}$, loss rate $m / \tau_{\text {chem }}$ ) and export out of the box (time constant $\tau_{\text {out }}$, loss rate $\left.m / \tau_{\text {out }}\right)$. The fraction $f$ of the pollutant removed by export is

$$
f=\frac{\text { export loss rate }}{\text { total loss rate }}=\frac{\frac{m}{\tau_{\text {out }}}}{\frac{m}{\tau_{\text {chem }}}+\frac{m}{\tau_{\text {out }}}}=\frac{1}{1+\frac{\tau_{\text {out }}}{\tau_{\text {chem }}}}
$$

The efficiency with which a pollutant emitted from the United States is exported to the global atmosphere
depends on its rate of chemical loss relative to the rate of ventilation. For the typical wind speed considered here, pollutants with lifetimes longer than 6 days against chemical loss are efficiently exported out of the United States $(f>0.5)$ while pollutants with shorter lifetimes are mostly removed within the United States and have relatively little global impact.

## 3. 2 Stratosphere-troposphere exchange

1. The ${ }^{90} \mathrm{Sr}$ inventories in the stratosphere and troposphere are affected by loss from radioactive decay $(L)$, transfer from the stratosphere to the troposphere $\left(F_{S T}\right)$, reverse transfer from the troposphere to the stratosphere $\left(F_{T S}\right)$, and deposition $(D)$. Deposition applies only in the troposphere. There were no ${ }^{90} \mathrm{Sr}$ emissions during the post-1962 period. The mass balance equations are:

$$
\begin{gathered}
\overline{d m}_{S}=F_{T S}-F_{S T}-L_{S} \\
{\frac{d m_{T S}}{d t}}^{T}=F_{S T}-F_{T S}-L_{T}-D
\end{gathered}
$$

The transfer rates $F_{S T}$ and $F_{T S}$ are related to the transfer rate constants $k_{S T}$ and $k_{T S}$ :

$$
\begin{aligned}
F_{S T} & =k_{S T} m_{S} \\
F_{T S} & =k_{T S} m_{T}
\end{aligned}
$$

The loss rates from radioactive decay are

$$
\begin{aligned}
L_{S} & =k_{d} m_{S} \\
L_{T} & =k_{d} m_{T}
\end{aligned}
$$

Here $k_{d}$ is the rate constant for radioactive decay; $k_{d}=\ln 2 / t_{1 / 2}=0.025 \mathrm{yr}^{-1}$, where $t_{1 / 2}=28 \mathrm{yr}$ is the halflife of ${ }^{90}$ Sr.

The loss rate from deposition is

$$
D=k_{D} m_{T}
$$

Here $k_{D}$ is the loss rate constant for deposition; $k_{D}=1 / \tau_{D}=0.1$ day $^{-1}$ where $\tau_{D}=10$ days is the lifetime against deposition in the troposphere.

Replacing in the mass balance equations:

$$
\begin{gathered}
\frac{d m_{S}}{d t}=k_{T S} m_{T}-\left(k_{S T}+k_{d}\right) m_{S} \\
\frac{d m_{T}}{\overline{d t}^{T}}=k_{S T} m_{S}-\left(k_{T S}+k_{d}+k_{D}\right) m_{T}
\end{gathered}
$$

2. Assuming that transfer of ${ }^{90} \mathrm{Sr}$ from the troposphere to the stratosphere $\left(F_{T S}\right)$ is negligible, the mass balance equation for $m_{S}$ becomes

$$
\frac{d m_{S}}{d t}=-\left(k_{S T}+k_{d}\right) m_{S}
$$

Integrating this equation yields:

$$
m_{S}(t)=m_{S}(0) e^{-\left(k_{S T}+k_{d}\right) t}
$$

Comparing to the observed decrease

$$
m_{S}(t)=m_{S}(0) e^{-k t}
$$

with $k=0.77 \mathrm{yr}^{-1}$, we obtain:

$$
k_{S T}=k-k_{d}
$$

so that $k_{S T}=0.75 \mathrm{yr}^{-1}$ and hence $\tau_{\mathrm{S}}=1 / k_{S T}=1.3 \mathrm{yr}$. Note that radioactive decay has negligible effect on the calculation of $\tau_{\mathrm{S}}$ because the lifetime of ${ }^{90} \mathrm{Sr}$ against radioactive decay is long compared to the residence time of air in the stratosphere.
3. Total air mass must be at steady state between the troposphere and the stratosphere,

$$
m_{S}^{\prime} k_{S T}=m_{T}^{\prime} k_{T S}
$$

and therefore

$$
\tau_{T}=\tau_{S}\left(\frac{m_{T}^{\prime}}{m_{S}^{\prime}}\right)
$$

Since the pressure at a given altitude is proportional to the mass of atmosphere overhead,

$$
\frac{m_{T}^{\prime}}{m_{S}^{\prime}}=\frac{P_{\text {surface }}-P_{\text {tropopause }}}{P_{\text {tropopause }}-P_{\text {stratopause }}}
$$

where $P_{\text {surface }}=1000 \mathrm{hPa}, P_{\text {tropopause }}=150 \mathrm{hPa}, P_{\text {stratopause }}=1 \mathrm{hPa}$. We find $m_{T}{ }^{\prime} / m_{S}{ }^{\prime}=5.7$ and hence $\tau_{\mathrm{T}}=$ 7.4 years. Compare to the lifetime $\tau_{\mathrm{D}}=10$ days of ${ }^{90} \mathrm{Sr}$ against deposition in the troposphere; the fraction of ${ }^{90} \mathrm{Sr}$ in the troposphere that is transferred back to the stratosphere is negligible, justifying our assumption in question 2.
4. Let $m$ represent the mass of HCFC in the troposphere. The HCFC loss rate by transfer to the stratosphere is $L_{T S}=m / \tau_{T}$, while the loss rate from oxidation is $L_{o x}=m / \tau_{o x}$ where $\tau_{o x}$ is the lifetime against oxidation. The fraction $f$ of emitted HCFC that penetrates the stratosphere is

$$
f=\frac{L_{T S}}{L_{T S}+L_{o x}}=\frac{\frac{1}{\tau_{T}}}{\frac{1}{\tau_{T}}+\frac{1}{\tau_{o x}}}=\frac{1}{1+\frac{\tau_{T}}{\tau_{o x}}}
$$

For HCFC-123, $\tau_{o x}=1.4$ years and $f=0.16$; for HCFC-124, $\tau_{o x}=5.9$ years and $f=0.44$.

## 3. 3 Interhemispheric exchange

1. We write mass balance equations for $m_{N}$ and $m_{S}$, and take the difference:

$$
\begin{gathered}
\frac{d m_{N}}{d t}=E+k m_{S}-k m_{N}-k_{c} m_{N} \\
\frac{d m_{S}}{d t}=k m_{N}-k m_{S}-k_{\mathrm{c}} m_{S} \\
\frac{d\left(m_{N}-m_{S}\right)}{d t}=E-\left(2 k+k_{c}\right)\left(m_{N}-m_{S}\right)
\end{gathered}
$$

In $1983, m_{N}-m_{S}=7 \mathrm{~kg}, E=15 \mathrm{~kg}$; assuming steady state for $\left(m_{N}-m_{S}\right)$ we obtain

$$
\begin{gathered}
\left(2 k+k_{c}\right)=\frac{E}{\left(m_{N}-m_{S}\right)} \\
k=\frac{1}{2}\left(\frac{E}{M_{N}-M_{S}}-k_{c}\right)=1.04 y r^{-1} \\
\tau=1 / k=.96 \mathrm{yr}
\end{gathered}
$$

2. Based on the equation:

$$
\frac{d\left(m_{N}-m_{S}\right)}{d t}=E-\left(2 k+k_{d}\right)\left(m_{N}-m_{S}\right)
$$

we see that the time scale for $\left(m_{N}-m_{S}\right)$ to relax to steady state is $1 /\left(2 k+k_{d}\right)=0.5 \mathrm{yr}$. The rise in $E$ is slow relative to this time scale so that ( $m_{N}-m_{S}$ ) has the time to continually adjust to steady state as $E$ increases.

## 3. 4 Long-range transport of acidity

We start from the puff model versions of the mass balance equations for $\mathrm{SO}_{2}$ and $\mathrm{H}_{2} \mathrm{SO}_{4}$ :

$$
\begin{gathered}
\frac{d\left[\mathrm{SO}_{2}\right]}{d t}=-k_{1}\left[\mathrm{SO}_{2}\right] \\
\frac{d\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]}{d t}=k_{1}\left[\mathrm{SO}_{2}\right]-k_{2}\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]
\end{gathered}
$$

Integration of the mass balance equation for $\mathrm{SO}_{2}$ yields as solution

$$
\left[\mathrm{SO}_{2}\right]=\left[\mathrm{SO}_{2}\right]_{o} e^{-k_{1} t}
$$

Replacing into the mass balance equation for $\mathrm{H}_{2} \mathrm{SO}_{4}$ :

$$
\begin{equation*}
\frac{d\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]}{d t}+k_{2}\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]=k_{1}\left[\mathrm{SO}_{2}\right]_{o} e^{-k_{1} t} \tag{1}
\end{equation*}
$$

We seek the general solution to (1) as the sum of the general solution to the homogeneous equation (right-hand-side equal zero) and a particular solution to the full equation (1). The general solution to the homogeneous equation is

$$
\left[H_{2} \mathrm{SO}_{4}\right]=A e^{-k_{2} t}
$$

where $A$ is an integration constant. In addition, we can see from the form of (1) that it must admit a solution of the form $B \exp \left(-k_{1} t\right)$ where $B=$ is a constant to be determined by substitution in the mass balance equation: we find $B=\left[\mathrm{SO}_{2}\right]_{\mathrm{O}} /\left(k_{2}-k_{1}\right)$. The general solution to (1) is therefore:

$$
\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]=A e^{-k_{2} t}+\frac{k_{1}\left[\mathrm{SO}_{2}\right]_{o}}{k_{2}-k_{1}} e^{-k_{1} t}
$$

We derive the value of the integration constant $A$ from the initial condition $\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]_{\mathrm{o}}=0$ at $t=0$ :

$$
A=-\frac{k_{1}\left[S O_{2}\right]_{o}}{k_{2}-k_{1}}
$$

and thus obtain the final solution for $\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]$ :

$$
\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]=\frac{k_{1}\left[\mathrm{SO}_{2}\right]_{o}}{k_{2}-k_{1}}\left(e^{-k_{1} t}-e^{-k_{2} t}\right)
$$

To obtain the solutions as a function of distance downwind of the power plants we simply replace $t=x / U$ in the expressions for $\left[\mathrm{SO}_{2}\right]$ and $\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]$.

The rate of acid deposition is $k_{2}\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]$ where $k_{2}$ is taken to be constant; thus the maximum in acid deposition corresponds to the maximum in $\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]$. Solving for $\mathrm{d}\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right] / \mathrm{dt}=0$,

$$
\frac{d}{d t}\left[H_{2} S O_{4}\right]=\frac{k_{1}\left[S O_{2}\right]_{o}}{k_{2}-k_{1}}\left(-k_{1} e^{-k_{1} t}+k_{2} e^{-k_{2} t}\right)
$$

yields

$$
t_{\max }=\frac{\ln \left(\frac{k_{1}}{k_{2}}\right)}{k_{1}-k_{2}}
$$

so that $t_{\max }=3.1$ days and $x_{\max }=u t_{\max }=1300 \mathrm{~km}$. Acid deposition is maximum 1300 km northeast of the power plants, i.e., somewhere over eastern Canada.

## 3. 5 Box vs. column model for an urban airshed

a) Steady-state box model:

$$
\begin{aligned}
& \text { Source of X (emission })=E / h\left(\text { molecules } \mathrm{cm}^{-3} \mathrm{~s}^{-1}\right) \\
& \text { Sink of } \mathrm{X}(\text { transport out })=U[X] / L\left(\text { molecules } \mathrm{cm}^{-3} \mathrm{~s}^{-1}\right)
\end{aligned}
$$

Source $=$ Sink: $E / h=U[X] / L \quad \Rightarrow \quad[X]=E L / U h$
b) Column model: consider an air column of height $h$ traveling at a wind speed $U$ through the urban area from $x=0$ to $x=L$. Over the urban area the source of X in the column is $E / h$, and there is no sink:

$$
\frac{d[X]}{d t}=\frac{E}{h}
$$

Replacing $d t=d x / U$, and integrating:

$$
U \frac{d[X]}{d x}=\frac{E}{h} \Rightarrow d[X]=\frac{E}{U h} d x \Rightarrow[X]=\frac{E x}{U h}
$$

Since this is a linear function the mean value of $[X]$ in the urban air is the value at $x=L / 2$, i.e., $[X]=E L / 2 U h$.

Thus the mean concentration in the column model is only half of that in the box model. The reason is that in the box model the residence time of X in the urban area is $\tau=L / U$ while in the column model it is $\tau=L / 2 U$ (representing the residence time of a molecule of X emitted as the column has already moved halfway across the urban area).

### 3.7 The Montreal protocol

1. The mass balance equation for $\mathrm{CFC}-12$ is

$$
\frac{d m}{d t}=E-k m
$$

where $k=0.01 \mathrm{yr}^{-1}$ is the rate constant for photolysis. The time-dependent solution is:

$$
m(t)=m(0) e^{-k t}+\frac{E}{k}\left(1-e^{-k t}\right)
$$

and the steady-state solution is

$$
m(\infty)=\frac{E}{k}
$$

In the original Montreal protocol, emissions were to stabilize at $50 \%$ of 1989 values: $E=$ $0.5 \times 4 \times 10^{8}=2 \times 10^{8} \mathrm{~kg} \mathrm{yr}^{-1}$. The resulting steady-state atmospheric mass of CFC-12 would be $m(\infty)=2 \times 10^{10} \mathrm{~kg}$, higher than the 1989 value. The 1989 value was far below the corresponding
steady state $\left(m(\infty)=4 \times 10^{10} \mathrm{~kg}\right.$ for $\left.E=4 \times 10^{8} \mathrm{~kg} \mathrm{yr}^{-1}\right)$, because emissions were increasing rapidly.
2. Amended Montreal protocol. For the $1989-1996$ period $\left(t=7\right.$ years), $m(0)=1.0 \times 10^{10} \mathrm{~kg}$ and $E=4 \times 10^{8} \mathrm{~kg} \mathrm{yr}^{-1}$. Substituting in the above time-dependent equation, we find the atmospheric mass of CFC-12 in 1996: $m=1.2 \times 10^{10} \mathrm{~kg}$.

For the 1996-2050 period $(t=54$ years $), m(0)=1.2 \times 10^{10} \mathrm{~kg}$ and $E=0$. We find $m=7.0 \times 10^{9} \mathrm{~kg}$ in 2050 , or $70 \%$ of the 1989 value.

For the 2050-2100 period $\left(t=50\right.$ years), $m(0)=7.0 \times 10^{9} \mathrm{~kg}$ and $E=0$. We find $m=4.2 \times 10^{9} \mathrm{~kg}$ in 2100 , or $40 \%$ of the 1989 value.
3. Delayed-action scenario: for the 1989-2006 period $(t=17$ years $), m(0)=1.3 \times 10^{10} \mathrm{~kg}$ and $E=$ $4 \times 10^{8} \mathrm{~kg} \mathrm{yr}^{-1}$, we find $m=1.5 \times 10^{10} \mathrm{~kg}$.

For the 2006-2050 period (44 years), $\mathrm{m}(0)=1.5 \times 10^{10} \mathrm{~kg}$ and $\mathrm{E}=0$. We find $\mathrm{m}=1.0 \times 10^{10} \mathrm{~kg}$ in 2050.

For the 2050-2100 period (50 years), $\mathrm{m}(0)=1.0 \times 10^{10} \mathrm{~kg}$ and $\mathrm{E}=0$. We find $\mathrm{m}=0.61 \times 10^{10} \mathrm{~kg}$ in 2100.

The cost of a 10-year delay in regulation is almost 50 years in results!

## SOLUTIONS TO PROBLEMS, CHAPTER 4

## 4. 1 Dilution of power plant plumes

1-C (unstable); 2-D (inversion); 3-A (unstable below stack, stable above); 4-B (stable below stack, unstable above)

## 4. 2 Short questions on atmospheric transport.

1. During summer, surface heating of the Earth's surface allows for deeper convection than in winter. Vertical ventilation of pollution is therefore faster than in winter. In winter, stronger thermal contrast (and hence stronger pressure gradient) between the tropics and the poles leads to stronger westerly winds at midlatitudes based on geostrophic balance. Horizontal ventilation of pollution is therefore faster than in summer.
2. Solar heating of the surface creates unstable conditions in the lower atmosphere. In an unstable atmosphere, both upward and downward motions are accelerated by buoyancy; both upward and downward transport of pollutants is therefore facilitated.
3. In the turbulent diffusion parameterization of turbulence, the flux $F=-K N d C / d z$ transports the pollutant always from regions of higher concentrations to regions of lower concentrations. For a pollutant emitted at the surface, the pollutant flux $F=-K N d C / d z$ must be upward and hence the mixing ratio must decrease with altitude ( $d C / d z$ must be negative). This result is consistent with the profile measured on day 1 but not with the profile measured on day 2 . The profile on day 2 can be explained by rapid vertical pumping of pollutant to high altitudes by deep convection somewhere upwind of the measurement site.
4. At night, the stability of the atmosphere prevents pollution emitted at 200 m altitude from reaching the surface. In early morning, solar heating of the surface gradually erodes the nighttime stability; the unstable mixed layer eventually reaches 200 m altitude at which point pollution from the power plant is brought down to the surface. As daytime heating continues the mixed layer grows, diluting the pollution from the power plant. The maximum surface concentrations are therefore in early morning when the mixed layer first reaches 200 m altitude.
5. Adiabatic sinking of a cloudy air parcel causes it to heat. The resulting evaporation of cloudwater consumes part of that heat. This process is exactly the reverse of the condensation of water in a rising air parcel, and the lapse rate $\Gamma_{\mathrm{W}}$ is the same in both cases. Thus a sinking cloudy air parcel accelerates in a conditionally unstable atmosphere $\left(-d T / d z>\Gamma_{\mathrm{W}}\right)$. In a deep convective cloud system, such as a thunderstorm, this mechanism allows rapid transport of air from the upper to the lower troposphere.
6. The turbulent flux is proportional to the concentration gradient: $F=-K N \partial C / \partial z$. For a well-mixed gas $\partial C / \partial z=0$ and hence the turbulent flux is zero.

## 4. 3 Seasonal motion of the ITCZ

We define a meteorological "northern hemisphere" as the world north of the ITCZ. Between January and July, air from the meteorological northern hemisphere is transferred to the meteorological southern hemisphere as the ITCZ moves north. From July to January the meteorological northern hemisphere expands, incorporating air from the meteorological southern hemisphere. The mass of air transferred from the meteorological northern to southern hemisphere between January and July is that contained in the band extending from latitude $5^{\circ} \mathrm{S}\left(\lambda_{1}\right)$ to $10^{\circ} \mathrm{N}\left(\lambda_{2}\right)$. We can assume that the mass of air in the band is
proportional to the surface area of the band since surface pressures are relatively uniform. The area of an elementary band $[\lambda, \lambda+d \lambda]$ is $2 \pi \mathrm{R}^{2} \cos \lambda \mathrm{~d} \lambda$ (simple geometry). By integration, the area of a finite band $\left[\lambda_{1}\right.$, $\lambda_{2}$ ] is $2 \pi R^{2}\left(\sin \lambda_{2}-\sin \lambda_{1}\right)$. Dividing by the total area of the hemisphere, we derive the fraction $f$ of air in the meteorological northern hemisphere that is transferred to the southern hemisphere over the course of one year:

$$
f=\frac{m\left[\lambda_{1}, \lambda_{2}\right]}{m\left[0, \frac{\pi}{2}\right]}=\sin \lambda_{2}-\sin \lambda_{1}=0.26
$$

This fraction corresponds to a time scale $1 / 0.26=3.9$ years for interhemispheric exchange, much longer than the observed time scale of 1 year. Seasonal motion in the mean latitude of the ITCZ is thus only a minor (though not totally negligible) contributor to interhemispheric exchange.

## 4. 4 A simple boundary layer model

1. A persistent subsidence inversion caps the PBL at 1.5 km altitude. At night, cooling of the surface produces a second inversion close to the surface; a shallow mixed layer still persists because of windinduced turbulence. In the daytime, heating of the surface gradually erodes the nighttime inversion and the mixed layer deepens as the day progresses. At sunset, surface cooling causes the mixed layer to collapse rapidly. The greatest weakness of this model is the assumption of a well-mixed remnant PBL (in fact, the remnant PBL is stable and would not be well mixed).
2. From midnight to 6 a.m., the concentration of $X$ increases linearly with time in the mixed layer while the concentration in the remnant PBL remains zero. During daytime from 6 a.m. to 6 p.m., the linear rise in the mixing depth causes dilution of the mixed layer by entrainment of air from the remnant PBL containing zero concentration of $X$. The mixed layer at 6 p.m. is about 6 times deeper than it was at 6 a.m., while the total amount of $X$ in the mixed layer is only 3 times as much; therefore the concentration of $X$ at 6 p.m. is half of what it was at 6 a.m.. The concentration of $X$ in the remant PBL remains zero throughout the day because there is no transfer of air from the mixed layer to the remnant PBL. After 6 p.m., the mixed layer collapses and air from the mixed layer is incorporated into the remnant PBL; the concentration in the mixed layer does not change but the remnant PBL now acquires the concentration of the mixed layer. From 6 p.m. to midnight the concentration of $X$ in the mixed layer increases linearly anew while the concentration in the remnant PBL remains constant.

## 4. 5 Breaking a nighttime inversion

1. Ventilation of the valley requires the establishment of an adiabatic lapse rate $-d T / d z=10 \mathrm{~K} \mathrm{~km}^{-1}$ in the lower atmosphere affected by the inversion $\left(0<z<z_{T}=0.5 \mathrm{~km}\right)$. The corresponding minimum temperature rise is shown as the dotted line in the Figure and is given by

$$
\Delta T(z)=a\left(z_{T}-z\right) \quad a=20 \mathrm{~K} \mathrm{~km}^{-1}
$$

2. Consider an atmospheric column $\left[0, z_{T}\right]$ of unit surface area. The heat input $Q$ to this column necessary to achieve $\Delta T(z)$ is

$$
Q=\rho C_{p} \int_{0}^{z_{T}} \Delta T(z) d z
$$

where we have integrated over the column $\left[0, z_{T}\right]$ the heating necessary for each column element of thickness $d z$ (mass $\rho d z$ ). Replacing the expression for $\Delta T(z)$ given above we obtain

$$
Q=\rho C_{p} \int_{0}^{z_{T}} a\left(z_{T}-z\right) d z=\frac{\rho C_{p} a z_{T}^{2}}{2}
$$

Substituting numerical values (SI units, to be safe!) $\rho=1 \mathrm{~kg} \mathrm{~m}^{-3}, C_{P}=1 \times 10^{3} \mathrm{~J} \mathrm{~kg}^{-1} \mathrm{~K}^{-1}, a=2 \times 10^{-2} \mathrm{~K} \mathrm{~m}^{-1}, z_{T}$ $=500 \mathrm{~m}$, we obtain $Q=2.5 \times 10^{6} \mathrm{~J} \mathrm{~m}^{-2}$.
3. Starting from dawn $\left(t_{0}\right)$, the sun begins to heat the surface. Over a time $d t$ the input of heat is $d Q=$ Fdt. The valley will be ventilated at the time $t_{1}$ when the accumulated heat has reached the value $Q$ derived in question 2 :

$$
Q=\int_{t_{0}}^{t_{1}} F d t
$$

Replacing the sinusoidal function $F(t)$ given in the problem, and introducing $t_{\text {noon }}=12$ p.m. and $\Delta t=24$
hours to stick with symbolic notation throughout:

$$
Q=F_{\max } \int_{t_{0}}^{t_{1}} \cos \frac{2 \pi\left(t-t_{\text {noon }}\right)}{\Delta t} d t=F_{\max } \frac{\Delta t}{2 \pi}\left[\sin \frac{2 \pi\left(t_{1}-t_{\text {noon }}\right)}{\Delta t}-\sin \frac{2 \pi\left(t_{0}-t_{\text {noon }}\right)}{\Delta t}\right]
$$

so that

$$
t_{1}=t_{\text {noon }}+\frac{\Delta t}{2 \pi} \operatorname{asin}\left[\frac{2 \pi Q}{F_{\text {max }} \Delta t}+\sin \frac{2 \pi\left(t_{0}-t_{\text {noon }}\right)}{\Delta t}\right]
$$

Substituting numerical values we obtain $t_{1}=10: 30$ a.m.

## 4. 6 Wet convection

1. Identify stable and unstable regions in the profile.

AB: $-d T / d z=10^{\circ} \mathrm{K} / \mathrm{km} \geq \Gamma \Rightarrow$ unstable atmosphere
$B C:-d T / d z=7.5^{\circ} \mathrm{K} / \mathrm{km}<\Gamma \Rightarrow$ stable atmosphere
CD: $-d T / d z=0 \ll \Gamma \Rightarrow$ very stable atmosphere
2. Cloud formation releases heat by condensation of water vapor, making the parcel more buoyant and facilitating its further rise. For a wet adiabatic lapse rate $\Gamma_{\mathrm{W}}=6 \mathrm{~K} \mathrm{~km}^{-1}$ the region $B C$ is conditionally unstable so that cloudy air parcels continue rising up to a maximum altitude $z_{\text {max }}$ in the region CD where their temperature reaches $T_{C D}=265 \mathrm{~K}$; at that point, since the surrounding atmosphere is isothermal at 265 K , further ascent is strongly suppressed. The altitude $z_{\max }$ is given by

$$
-\frac{T_{C D}-T_{B}}{z_{\max }-z_{B}}=\Gamma_{W} \Rightarrow z_{\max }=z_{B}+\frac{T_{C D}-T_{B}}{\Gamma_{W}}
$$

Substituting $z_{B}=2 \mathrm{~km}, T_{C D}=265 \mathrm{~K}$, and $T_{B}=280 \mathrm{~K}$, we obtain $z_{\text {max }}=4.5 \mathrm{~km}$.
3. Pollutants released at the surface mix up to 2 km altitude in clear sky and up to 4.5 km in cloudy air; cloud formation greatly improves ventilation.

## 4. 7 Scavenging of water in a thunderstorm

The fraction of water vapor removed by precipitation in the updraft is $f=\left(C_{0}-C_{\text {top }}\right) / C_{0}$, where $C_{0}$ and $C_{\text {top }}$ are the water vapor mixing ratios at the base and at the top of the updraft, respectively.

Base of updraft: $z=1 \mathrm{~km}, T=25^{\circ} \mathrm{C}, P_{\mathrm{H} 2 \mathrm{O}, \mathrm{SAT}}=32 \mathrm{hPa}, P=P(0) \exp [-z / \mathrm{H}]=870 \mathrm{hPa}$; therefore $\mathrm{C}_{o}=32 / 870$ $=0.037 \mathrm{~mol} / \mathrm{mol}$.

Top of updraft: $z=15 \mathrm{~km}, T=25-\Gamma_{\mathrm{W}} z=-31^{\circ} \mathrm{C}, P_{\mathrm{H} 2 \mathrm{O}, S A T}=0.5 \mathrm{hPa}, P=P(0) \exp [-z / \mathrm{H}]=130 \mathrm{hPa}$; therefore $C_{\text {top }}=0.5 / 130=3.8 \times 10^{-3} \mathrm{~mol} / \mathrm{mol}$.

The fraction of water removed by precipitation is $\mathrm{f}=1-\left(3.8 \times 10^{-3} / 0.037\right)=90 \%$.

## 4. 8 Global source of methane

1. Yes, we would expect $\mathrm{CH}_{4}$ to be well-mixed in the troposphere because the lifetime of $\mathrm{CH}_{4}$ (9 years) is much longer than the average time for mixing of the troposphere (1-2 years).
2. We write a mass balance equation for $\mathrm{CH}_{4}$ in the troposphere:

$$
\frac{d N}{d t}=E-L_{t r o p}-S_{T S}
$$

where

- $N$ is the total number of moles of $\mathrm{CH}_{4}$ in the troposphere; $N=C f N_{a}$ and $d N / d t=f N_{a} d C / d t$ where $C=$ 1700 ppbv is the mixing ratio of $\mathrm{CH}_{4}, d \mathrm{C} / d t=10 \mathrm{ppbv} \mathrm{yr}^{-1}$ is the growth rate of $\mathrm{CH}_{4}, N_{a}=1.8 \times 10^{20}$ moles is the total number of moles of air in the atmosphere (chapter 2), and $f=0.85$ is the fraction of that total in the troposphere (taking a 150 hPa tropopause).
- $\quad E$ (moles $\mathrm{yr}^{-1}$ ) is the global emission rate of $\mathrm{CH}_{4}$, which we wish to derive.
- $L_{\text {trop }}\left(\right.$ moles $\mathrm{yr}^{-1}$ ) is the global loss rate of $\mathrm{CH}_{4}$ from oxidation in the troposphere; $L_{\text {trop }}=N / \tau_{\text {ox }}$ where $\tau_{\mathrm{ox}}=9$ years is the lifetime of $\mathrm{CH}_{4}$ in the troposphere.
- $S_{T S}\left(\right.$ moles $\left.\mathrm{yr}^{-1}\right)$ is the net flow rate of $\mathrm{CH}_{4}$ from the troposphere to the stratosphere. For now we assume $S_{T S}=0$.

Replacing in the mass balance equation we obtain:

$$
\begin{gathered}
E=f N_{a} \frac{d C}{d t}+\frac{f N_{a} C}{\tau_{o x}}=f N_{a}\left(\frac{d C}{d t}+\frac{C}{\tau_{o x}}\right) \\
=0.85 \times 1.8 \times 10^{20}\left(10 \times 10^{-9}+\frac{1700 \times 10^{-9}}{9}\right)=3.0 \times 10^{13} \mathrm{moles} \mathrm{yr}^{-1}
\end{gathered}
$$

3.1 We write a mass balance for $\mathrm{CH}_{4}$ in the stratosphere, assuming steady state:

$$
S_{T S}=L_{\text {strat }}
$$

where $L_{s t r a t}$ is the loss rate of $\mathrm{CH}_{4}$ in the stratosphere; $S_{T S}=A F_{T S}$ where $A$ is the surface area of the Earth and $F_{T S}$ is the mean flux of $\mathrm{CH}_{4}$ across the tropopause. From the eddy diffusion formulation of the turbulent flux, $F_{T S}$ is given by

$$
F_{T S}=\left[-K_{z} n_{a} \frac{d C}{d z}\right]_{\text {tropopause }}
$$

and hence

$$
L_{\text {strat }}=-A\left[K_{z} n_{a} \frac{d C}{d z}\right]_{\text {tropopause }}
$$

Here $K_{z}$ and $d C / d z$ are not to be evaluated exactly at the tropopause (because of discontinuity in $d C / d z$ ) but just above.
3.2 We need to calculate $d C / d z$ in the stratosphere. From

$$
C(z)=C\left(z_{t}\right) e^{\left[-\frac{\left(z-z_{t}\right)}{h}\right]}
$$

we obtain

$$
\frac{d C}{d z}=C\left(z_{t}\right)\left(-\frac{1}{h}\right) e^{\left[-\frac{\left(z-z_{t}\right)}{h}\right]}
$$

Just above the tropopause $\left(z \approx z_{t}\right)$,

$$
\left.\frac{d C}{d z}\right|_{\text {tropopause }}=\frac{-C\left(z_{t}\right)}{h}
$$

where $C\left(z_{t}\right)=1700 \mathrm{ppbv}$ and $h=60 \mathrm{~km}$. We replace into the equation from question 3.1, with the numerical values $K_{z}=7 \times 10^{-1} \mathrm{~m}^{2} \mathrm{~s}^{-1}$ and $n_{a}=5 \times 10^{24}$ molecules $\mathrm{m}^{-3}$, and including $A=5.1 \times 10^{14} \mathrm{~m}^{2}$ for the surface area of the Earth. Note that the resulting $L_{\text {strat }}$ is in units of molecules s ${ }^{-1}$.

$$
\begin{gathered}
L_{\text {strat }}=-A\left[K_{z} n_{a} \frac{d C}{d z}\right]_{\text {tropopause }}=\frac{A K_{z} n_{a} C\left(z_{t}\right)}{h} \\
=\frac{5.1 \times 10^{14} \times 7 \times 10^{-1} \times 5 \times 10^{24} \times 1700 \times 10^{-9}}{60 \times 10^{3}}=5.1 \times 10^{28} \text { molecules s }^{-1}=2.7 \times 10^{12}{ }_{\mathrm{moles} \mathrm{yr}}-1
\end{gathered}
$$

Replacing now $S_{T S}=L_{\text {strat }}$ in the mass balance equation for $\mathrm{CH}_{4}$ in the troposphere:

$$
\frac{d N}{d t}=E-L_{\text {trop }}-L_{\text {strat }}
$$

we obtain an improved estimate of $E$ :

$$
E=3.0 \times 10^{13}+2.7 \times 10^{12}=3.3 \times 10^{13} \text { moles } \mathrm{yr}^{-1}
$$

## 4. 9 Role of molecular diffusion in atmospheric transport

1. We use the Einstein diffusion equation to find the average time $\Delta t$ needed for a molecule to travel a distance $\Delta x=1 \mathrm{~m}$ by molecular diffusion:

$$
\Delta t=\frac{(\Delta x)^{2}}{2 D}=\frac{(\Delta x)^{2}}{2 D_{o}} \frac{P}{P_{o}}=\frac{(\Delta x)^{2}}{2 D_{o}} \exp \left[-\frac{z}{H}\right]
$$

where we have replaced $D=D_{o}\left(P_{o} / P\right)$ and the Barometric Law $P=P_{o} \exp [-z / H] ; H=7.4 \mathrm{~km}$ is the atmospheric scale height. Since molecular diffusion is isotropic, $\Delta x$ applies to any direction (vertical or horizontal).

From the above equation with $\Delta x=1 \mathrm{~m}$ and $D_{\mathrm{o}}=0.2 \mathrm{~cm}^{2} \mathrm{~s}^{-1}$ we find $\Delta t=6.9$ hours at $z=0 \mathrm{~km}, \Delta t=1.8$ hours at $z=10 \mathrm{~km}, \Delta t=0.03 \mathrm{~s}$ at $z=100 \mathrm{~km}$. We see that molecular diffusion is very slow compared to typical time scales for atmospheric motion in the lowest scale heights of the atmosphere. At 10 km , the molecular diffusion coefficient is $D=0.8 \mathrm{~cm}^{2} \mathrm{~s}^{-1}$; compare to a typical turbulent diffusion coefficient $K_{z} \sim$ $10^{5} \mathrm{~cm}^{2} \mathrm{~s}^{-1}$. At 100 km , molecular diffusion is fast because the air density is low so that the mean free path between collisions is long.
2. For molecular diffusion to be more important than turbulent diffusion, we must have

$$
D>K_{z} \Rightarrow D_{o} \exp \left[\frac{z}{H}\right]>K_{z} \Rightarrow z>H \ln \frac{K_{z}}{D_{o}}=7.4 \ln \frac{1 \times 10^{5}}{0.2}=97 \mathrm{~km}
$$

Molecular diffusion becomes the dominant mechanism for vertical transport above 100 km .

## 4. 10 Vertical transport near the surface

The vertical flux of the species is given by

$$
F=-K_{z} n_{a} \frac{d C}{d z}=-\alpha z n_{a} \frac{d C}{d z}
$$

from which we obtain a relationship between $C$ and $z$,

$$
d C=-\frac{F}{\alpha n_{a}} \frac{d z}{z}
$$

Since the only sink for the species is reaction at the Earth' surface, $F$ at steady state is independent of $z$ (the vertical flux is conserved). In addition, near the surface we can neglect vertical changes in the air density $n_{a}$. Integration of the above equation between any two altitudes $z_{1}$ and $z_{2}$ yields therefore a logarithmic increase of $C$ with altitude:

$$
C\left(z_{2}\right)=C\left(z_{1}\right)-\frac{F}{\alpha n_{a}}\left(\ln z_{2}-\ln z_{1}\right)
$$

Note that $C$ increases with altitude in the above equation because $F$ is negative (it is directed toward the surface).

## SOLUTIONS TO PROBLEMS, CHAPTER 5

## 5. 1 Turbulent diffusion coefficient

1. The one-dimensional continuity equation includes terms from vertical transport (parameterized by a turbulent diffusion coefficient) and chemical loss. Emission of ${ }^{222} \mathrm{Rn}$ at the surface is a boundary condition and does not enter into the equation.

$$
\frac{\partial n}{\partial t}=\frac{\partial}{\partial z}\left[K N \frac{\partial C}{\partial z}\right]-k n
$$

2. In the above equation we replace $C(z)=C(0) \exp (-z / h), \partial n / \partial t=0$ (steady state), and

$$
n=N C=N(0) C(0) \exp \left[-\left(\frac{1}{H}+\frac{1}{h}\right)\right]
$$

where $N$ is the air density. The result is

$$
0=\frac{\partial}{\partial z}\left[-\frac{K}{h} N_{o} C_{o} e^{-z\left(\frac{1}{H}+\frac{1}{h}\right)}\right]-k N_{o} C_{o} e^{-z\left(\frac{1}{H}+\frac{1}{h}\right)}
$$

which yields upon further derivation

$$
\frac{K}{h}\left(\frac{1}{H}+\frac{1}{h}\right)=k
$$

Rearranging,

$$
K=\frac{k h}{\frac{1}{H}+\frac{1}{h}}=1.3 \times 10^{5} \mathrm{~cm}^{2} \mathrm{~s}^{-1}
$$

3. The emission flux $E$ of ${ }^{222} \mathrm{Rn}$ from the soil is given by the turbulent diffusion flux at $z=0$ :

$$
E=-\left.K n_{a}(0) \frac{\partial C}{\partial z}\right|_{z=0}
$$

Replacing $C(z)=C(0) \exp (-z / h)$, we obtain

$$
E=\frac{K n_{a}(0)}{h} C(0)=\frac{K n(0)}{h}=\frac{1.3 \times 10^{5} \times 2}{3 \times 10^{5}}=0.87 \text { atoms } \mathrm{cm}^{-2} \mathrm{~s}^{-1}
$$

4. By rearranging the solution to question (2) we obtain a quadratic equation for $h$ for which the solution is

$$
h=\frac{\frac{K}{k H} \pm \sqrt{\left(\frac{K}{k H}\right)^{2}+\frac{4 K}{k}}}{2}
$$

In this manner we can derive $h$ for any gas of known $k$, assuming $K$ to be constant in the atmosphere.

The residence time of water vapor in the atmosphere is 13 days. Assuming the loss of water by precipitation to be a continuous first-order process, the corresponding loss rate constant is $k=1 /(13$ days $)$ $=8.9 \times 10^{-7} \mathrm{~s}$. Substituting in the above equation gives $h=5.0 \mathrm{~km}$ for water vapor.

## SOLUTIONS TO PROBLEMS, CHAPTER 6

## 6. 1 Short questions on the oxygen cycle

1. The statement is wrong. The tropical rainforests are actually not net sources of oxygen because the $\mathrm{O}_{2}$ generated during the production of organic carbon by photosynthesis is eventually consumed by oxidation of this organic carbon back to $\mathrm{CO}_{2}$ when the plant dies.
2. The developer's reasoning is that cutting down mature trees and sealing them against oxidation will prevent the $\mathrm{O}_{2}$ generated during the growth of the tree to be consumed by oxidizing organic carbon when the tree decays. In this manner $\mathrm{O}_{2}$ levels will increase. The flaw in the reasoning is that the increase in $\mathrm{O}_{2}$ will be limited by the amount of atmospheric $\mathrm{CO}_{2}$ available for photosynthesis. Since atmospheric $\mathrm{CO}_{2}$ is less than $0.2 \%$ of atmospheric $\mathrm{O}_{2}$, we will run out of $\mathrm{CO}_{2}$ before having produced any significant increase in $\mathrm{O}_{2}$. So the plan would not work.
3. The $\mathrm{CO}_{2}$ produced in the bacterial reaction will eventually bubble out of the ocean and be consumed by photosynthesis, generating $\mathrm{O}_{2}$. Another (equivalent) perspective is that the reaction oxidizes organic carbon to $\mathrm{CO}_{2}$ by using $\mathrm{Fe}_{2} \mathrm{O}_{3}$ and $\mathrm{H}_{2} \mathrm{SO}_{4}$ as oxygen sources, i.e., without consuming $\mathrm{O}_{2}$. In this manner the $\mathrm{O}_{2}$ previously generated in the production of the organic carbon is not consumed in the eventual oxidation of this organic carbon, resulting in a net $\mathrm{O}_{2}$ source.

By summing the reaction and the eventual photosynthesis of the $\mathrm{CO}_{2}$ produced,

$$
\begin{gathered}
2 \mathrm{Fe}_{2} \mathrm{O}_{3}+8 \mathrm{H}_{2} \mathrm{SO}_{4}+15 \mathrm{CH}_{2} \mathrm{O} \rightarrow 4 \mathrm{FeS}_{2}+15 \mathrm{CO}_{2}+23 \mathrm{H}_{2} \mathrm{O} \\
15 \mathrm{CO}_{2}+15 \mathrm{H}_{2} \mathrm{O} \rightarrow 15 \mathrm{CH}_{2} \mathrm{O}+15 \mathrm{O}_{2} \\
2 \mathrm{Fe}_{2} \mathrm{O}_{3}+8 \mathrm{H}_{2} \mathrm{SO}_{4} \rightarrow 4 \mathrm{FeS}_{2}+8 \mathrm{H}_{2} \mathrm{O}+15 \mathrm{O}_{2} \quad \text { (net) }
\end{gathered}
$$

we see that the net effect of the reaction is to convert $\mathrm{Fe}_{2} \mathrm{O}_{3}$ and $\mathrm{H}_{2} \mathrm{SO}_{4}$ to $\mathrm{FeS}_{2}, \mathrm{H}_{2} \mathrm{O}$, and $\mathrm{O}_{2}$. The $\mathrm{Fe}_{2} \mathrm{O}_{3}$ and $\mathrm{H}_{2} \mathrm{SO}_{4}$ originate in turn from oxidation of $\mathrm{FeS}_{2}$ in the lithosphere by the reverse reaction, closing the $\mathrm{O}_{2}$ cycle. The bacterial reaction is therefore part of the atmosphere-lithosphere cycle of oxygen.
4. Most H atoms in the atmosphere are present as $\mathrm{H}_{2} \mathrm{O}$. Photolysis of $\mathrm{H}_{2} \mathrm{O}$ frees H atoms. When these H atoms escape to space, they leave behind the O atoms which are then eventually converted to $\mathrm{O}_{2}$ (the dominant form of oxygen in the atmosphere). If the H atoms do not escape to space, they recombine with O atoms to regenerate $\mathrm{H}_{2} \mathrm{O}$ and there is no net production of $\mathrm{O}_{2}$.

The H atom escape rate is $5.4 \times 10^{7} \mathrm{~kg} \mathrm{yr}^{-1}=5.4 \times 10^{10}$ moles $\mathrm{yr}^{-1}$. Essentially all of the escaping H originates from breakdown of the $\mathrm{H}_{2} \mathrm{O}$ molecule, and the resulting net source of O atoms to the atmosphere is $2.7 \times 10^{10}$ moles $\mathrm{yr}^{-1}=4.3 \times 10^{8} \mathrm{~kg} \mathrm{yr}^{-1}$. Assuming that the rate has remained constant since the beginning of the Earth $4.5 \times 10^{9}$ years ago, the total amount of $\mathrm{O}_{2}$ produced by this mechanism is $1.9 \times 10^{18} \mathrm{~kg}$. In comparison, the organic carbon inventory in sediments indicates that photosynthesis of primeval $\mathrm{CO}_{2}$ in the early Earth must have provided an $\mathrm{O}_{2}$ source of $3.2 \times 10^{19} \mathrm{~kg}$ (see exercise in chapter 6). Photosynthesis of primeval $\mathrm{CO}_{2}$ thus played a more important role than photolysis of $\mathrm{H}_{2} \mathrm{O}$ as an original source of $\mathrm{O}_{2}$ to the atmosphere.
5. The source of $\mathrm{O}_{2}$ from photosynthesis is limited to spring and summer, while the sink of $\mathrm{O}_{2}$ from oxidation of dead biomass is more evenly spread over the year. We expect therefore a summer peak for $\mathrm{O}_{2}$ concentrations. The seasonal variation of $\mathrm{O}_{2}$ is the reverse of that of $\mathrm{CO}_{2}$,
since the source of $\mathrm{O}_{2}$ is a sink of $\mathrm{CO}_{2}$ and vice versa. Considering that there is a 1:1 $\mathrm{O}_{2}: \mathrm{CO}_{2}$ stoichiometry in these sources and sinks, the amplitudes of the seasonal cycles should be the same for both $\mathrm{O}_{2}$ and $\mathrm{CO}_{2}$. The time series of $\mathrm{CO}_{2}$ at Mauna Loa, Hawaii, shows about a 3 ppbv seasonal amplitude (Fig 6-7 of sourcebook) and the same seasonal amplitude should apply to $\mathrm{O}_{2}$.

## 6. 2 Short questions on the carbon cycle

1. Uptake of $\mathrm{CO}_{2}$ by the oceans follows the stoichiometry

$$
\mathrm{CO}_{2}(\mathrm{~g})+\mathrm{CO}_{3}{ }^{2-} \stackrel{\mathrm{H}_{2} \mathrm{O}}{\Leftrightarrow} 2 \mathrm{HCO}_{3}^{-}
$$

Removing $\mathrm{CO}_{3}{ }^{2-}$ by coral formation will push the equilibrium to the left, releasing $\mathrm{CO}_{2}$ to the atmosphere. It may seem counterintuitive that by stocking carbon in the oceans through coral formation one would increase $\mathrm{CO}_{2}$; the key is that coral formation removes alkalinity $\left(\mathrm{CO}_{3}{ }^{2-}\right)$ from the ocean.
2. The residence time of air in the stratosphere is $1-2$ years, so that $\mathrm{CO}_{2}$ concentrations in the stratosphere represent those found in the troposphere 1-2 years before. The growth rate of $\mathrm{CO}_{2}$ in the troposphere is $1-2 \mathrm{ppmv} \mathrm{yr}^{-1}$, and the time lag for transfer of air from the troposphere to the stratosphere thus results in a 1-2 ppmv difference in concentrations between the two reservoirs.
3. No, because food production involves photosynthesis by crops which is a source of $\mathrm{O}_{2}$ and balances exactly the source of $\mathrm{CO}_{2}$ when this food is ingested.
4. Melting of the polar ice caps freshens the water of the polar surface oceans, making it lighter and hence less likely to sink to the deep ocean. The decrease in deep water formation slows down the uptake of $\mathrm{CO}_{2}$ by the ocean, and the resulting increase of $\mathrm{CO}_{2}$ in the atmosphere represents a positive feedback to global warming.
5. The statement is not intrinsically correct although it may have some political truth. Planting trees does reduce the stock of carbon present in the atmosphere as $\mathrm{CO}_{2}$. Note that the amount of organic carbon in the biosphere is larger than the amount of $\mathrm{CO}_{2}$ in the atmosphere, so that growing the biosphere does give us leverage for decreasing $\mathrm{CO}_{2}$. Although the organic carbon in a tree returns to the atmosphere when the tree dies ("in less than a century"), as long as the forest is maintained a new tree will grow in its place. The catch is that a plan to reduce $\mathrm{CO}_{2}$ by growing the biosphere requires a long-term commitment to the preservation of the stock of organic carbon in the new ecosystems. If these stocks are allowed to return to the atmosphere as $\mathrm{CO}_{2}$ (as for example if the dying trees are not replaced, or if the forest is cut or burned to return to its original use) then the gains will be lost.

## 6. 3 Atmospheric residence time of helium

1. Helium is sufficiently light to overcome Earth's gravity and escape to outer space.
2. The mass $m_{A r}$ of argon in the present-day atmosphere is:

$$
m_{A r}=C_{A r} \frac{M_{A r}}{M_{\text {air }}} m_{\text {air }}=9340 \times 10^{-6} \times \frac{40}{29} \times 5.2 \times 10^{18}=6.7 \times 10^{16} \mathrm{~kg}
$$

Since there is no sink for argon in the atmosphere, the mean source rate $\bar{P}_{\text {Ar }}$ over the Earth's history $\Delta t=4.5 \times 10^{9}$ years is

$$
\bar{P}_{A r}=\frac{m_{A r}}{\Delta t}=1.5 \times 10^{7} \mathrm{~kg} \mathrm{yr}^{-1}
$$

3. The production rate of argon at any given time in Earth's history depends on the remaining mass $m_{K}$ of ${ }^{40} \mathrm{~K}$ in the Earth's interior:

$$
P_{A r}(t)=k m_{K}(t)
$$

This mass $m_{K}$ has been decreasing exponentially since the formation of the Earth:

$$
m_{K}(t)=m_{K}(0) e^{-k t}
$$

so that

$$
P_{A r}(t)=k m_{K}(0) e^{-k t}
$$

The mean value of $P_{A r}$ over time $\Delta t$ is then given by
$\bar{P}_{A r}=\frac{1}{\Delta t} \int_{0}^{\Delta t} P_{A r}(t) d t=\frac{1}{\Delta t} \int_{0}^{\Delta t} k m_{K}(0) e^{-k t} d t=\frac{k m_{K}(0)}{\Delta t} \int_{0}^{\Delta t} e^{-k t} d t=\frac{m_{K}(0)}{\Delta t}\left(1-e^{-k \Delta t}\right)$
and the value of $P_{A r}$ at time $\Delta t$ is given by

$$
P_{A r}(\Delta t)=k m_{K}(0) e^{-k \Delta t}
$$

Taking the ratio between the two:

$$
\frac{P_{A r}(\Delta t)}{\bar{P}_{A r}}=\frac{k \Delta t}{\exp (k \Delta t)-1}=0.23
$$

which is the desired result.
4. From the previous equation, the present-day source of argon is
$P_{A r}(\Delta t)=0.23 \bar{P}_{\mathrm{Ar}}=0.23 \times 1.5 \times 10^{7}=3.5 \times 10^{6} \mathrm{~kg} \mathrm{yr}^{-1}$
and, since we are told that the source of helium is the same,
$P_{H e}(\Delta t)=P_{A r}(\Delta t)=3.5 \times 10^{6} \mathrm{~kg} \mathrm{yr}^{-1}$
The present-day mass $m_{H e}(\Delta t)$ of helium in the atmosphere can be derived from the observed mixing ratio of 5.2 ppmv :

$$
m_{H e}=C_{H e} \frac{M_{H e}}{M_{a i r}} m_{a i r}=5.2 \times 10^{-6} \times \frac{4}{29} \times 5.2 \times 10^{18}=3.7 \times 10^{12} \mathrm{~kg}
$$

Assuming steady state for helium, the atmospheric lifetime of He against escape to outer space is

$$
\tau_{H e}=\frac{m_{H e}(\Delta t)}{P_{H e}(\Delta t)}=\frac{3.7 \times 10^{12}}{3.5 \times 10^{6}}=1.1 \text { million years }
$$

## 6. 4 Methyl bromide

1.1 The lifetime of $\mathrm{CH}_{3} \mathrm{Br}$ against oxidation in the atmosphere is sufficiently long ( 2.0 years) that its atmospheric mixing ratio $C$ can be assumed uniform. We can relate $C$ to the sea-level values of the partial pressure $P_{\text {CH3Br }}$ and the total atmospheric pressure $P_{a}$ :

$$
C=\frac{P_{C H 3 B r}}{P_{a}}
$$

The total number of moles of $\mathrm{CH}_{3} \mathrm{Br}$ in the atmosphere is then

$$
n_{a t m}=C N_{a}=\frac{P_{C H 3 B r}}{P_{a}} N_{a}
$$

where $N_{a}=1.8 \times 10^{20}$ moles is the total number of moles of air in the atmosphere. The total number of moles of $\mathrm{CH}_{3} \mathrm{Br}$ in the oceanic mixed layer can be similarly related to the sea-level partial pressure of $\mathrm{CH}_{3} \mathrm{Br}$ :

$$
n_{\text {ocean }}=V\left[\mathrm{CH}_{3} \mathrm{Br}(a q)\right]=V K_{H} P_{\mathrm{CH} 3 \mathrm{Br}}
$$

where $V=3.6 \times 10^{19} 1$ is the volume of the oceanic mixed layers. Therefore,

$$
\frac{n_{\text {ocean }}}{n_{a t m}}=\frac{V K_{H} P_{a}}{N_{a}}=\frac{3.6 \times 10^{19} \cdot 0.11 \cdot 1}{1.8 \times 10^{20}}=0.022
$$

There is 45 times more $\mathrm{CH}_{3} \mathrm{Br}$ in the atmosphere than in the oceanic mixed layer.
1.2 The atmospheric lifetime $\tau_{\text {hyd }}$ of $\mathrm{CH}_{3} \mathrm{Br}$ against hydrolysis in the ocean is defined as

$$
\tau_{\text {hyd }}=\frac{n_{\text {atm }}}{k_{0} n_{\text {ocean }}}
$$

Note that we cannot take $n_{\text {atm }} / n_{\text {ocean }}$ from the answer to question 1.1 because loss by hydrolysis ( $k_{o}>k_{2}$ ) reduces $n_{\text {ocean }}$ below equilibrium with the gas phase (if there were no hydrolysis then steady state would give us $n_{\text {ocean }} / n_{\text {atm }}=k_{1} / k_{2}=0.023$, which is the equilibrium value from the previous question). Accounting for hydrolysis, we write the steady state equation for $\mathrm{CH}_{3} \mathrm{Br}(\mathrm{aq})$ :

$$
k_{1} n_{a t m}=\left(k_{o}+k_{2}\right) n_{\text {ocean }}
$$

and replace in the above equation for $\tau_{\text {hyd }}$ :

$$
\tau_{\text {hyd }}=\frac{k_{o}+k_{2}}{k_{o} k_{1}}=3.3 \text { years }
$$

1.3 The lifetime of $\mathrm{CH}_{3} \operatorname{Br}(\mathrm{aq})$ against hydrolysis is $1 / k_{o}=0.025$ years, which is too short to allow significant transfer to the deep ocean (the residence time of water in the oceanic mixed layer is 20 years). Therefore the deep ocean does not represent an important reservoir for $\mathrm{CH}_{3} \mathrm{Br}$, in contrast to $\mathrm{CO}_{2}$.
1.4 The atmospheric lifetime $\tau$ of $\mathrm{CH}_{3} \mathrm{Br}$ reflects the contributions of sinks from atmospheric oxidation ( $\tau_{\mathrm{ox}}=2.0$ years) and hydrolysis in the ocean ( $\tau_{\mathrm{hyd}}=3.3$ years) operating in parallel:

$$
\tau=\left(\tau_{o x}^{-1}+\tau_{h y d}^{-1}\right)^{-1}=1.2 \text { years }
$$

1.5 Methylbromide emitted to the troposphere can be removed by the processes described above (rate constant $k^{\prime}=1 / \tau$ ) or by transport to the stratosphere (rate constant $k_{T S}$ ). The fraction $f$ transported to the stratosphere is therefore

$$
f=\frac{k_{T S}}{k^{\prime}+k_{T S}}=\frac{0.14}{0.83+0.14}=0.14
$$

$14 \%$ of the emitted $\mathrm{CH}_{3} \mathrm{Br}$ enters the stratosphere and is therefore active in depletion of the stratospheric ozone layer.
2.1 We write the steady-state equation for $m_{\mathcal{S}}$, assuming no emissions in the southern hemisphere:

$$
k m_{N}=\left(k+k^{\prime}\right) m_{S} \Rightarrow R=\frac{m_{N}}{m_{S}}=1+\frac{k^{\prime}}{k}=1+\frac{0.8}{0.9}=1.9
$$

2.2 Let $A$ represent the anthropogenic source (assumed to be located exclusively in the northern hemisphere) and $B$ represent the biogenic source (distributed equally between the two hemispheres). We write the steady-state equations for the total atmospheric mass $m=m_{N}+m_{S}$ of $\mathrm{CH}_{3} \mathrm{Br}$ in the atmosphere, and for $m_{S}$ separately (note that a third equation for $m_{N}$ separately would be redundant):

$$
\begin{array}{r}
A+B=k^{\prime} m \\
\frac{B}{2}+k m_{N}=\left(k+k^{\prime}\right) m_{S} \tag{2}
\end{array}
$$

We now divide the second equation by $m_{S}$, and replace $R=m_{N} / m_{S}$ and $m_{S}=m /(1+R)$ :

$$
\begin{equation*}
\frac{B(1+R)}{2 m}+k R=k+k^{\prime} \Rightarrow B=\frac{2 m}{1+R}\left(k+k^{\prime}-k R\right) \tag{3}
\end{equation*}
$$

The biogenic fraction $f$ of the global source is

$$
\begin{equation*}
f=\frac{B}{A+B} \tag{4}
\end{equation*}
$$

Replacing (1) and (3) into (4):

$$
f=\frac{\frac{2 m}{1+R}\left(k+k^{\prime}-k R\right)}{k^{\prime} m}=\frac{2\left(k+k^{\prime}-k R\right)}{(1+R) k^{\prime}}
$$

Substituting the observed value $R=1.3$, and numerical values for $k$ and $k^{\prime}$, we obtain $f=0.58$. Thus $58 \%$ of the global source of $\mathrm{CH}_{3} \mathrm{Br}$ must be biogenic.
2.3 There is no contradiction. Methyl bromide is produced biogenically in the oceans; a fraction is lost by hydrolysis in the ocean while the rest escapes to the atmosphere. The atmospheric fraction may be oxidized in the atmosphere or eventually return to the ocean and get hydrolyzed. Hydrolysis in the
oceans also acts as a sink for anthropogenic $\mathrm{CH}_{3} \mathrm{Br}$.

## 6. 5 The nitrogen cycle

1. Residence time $\tau=$ (inventory)/(flow out). Inventories are in Tg N , flows are in $\mathrm{Tg} \mathrm{Nyr}{ }^{-1}$; the resulting values for $\tau$ are in units of years.

Atmospheric $\mathrm{N}_{2}: \tau=3.9 \times 10^{9} /(80+160+30+20)==13$ million years
Atmospheric fixed $\mathrm{N}: \tau=3 /(80+30)=2.7 \times 10^{-2}$ years $=10$ days
Land biota: $\tau=1.0 \times 10^{4} / 2500=4$ years
Land soil: $\tau=7 \times 10^{4} /(2300+130+80+40)=27$ years
Ocean biota: $\tau=1000 /(1600+100)=0.59$ years $=7$ months
Deep ocean: $\tau=8 \times 10^{5} /(1600+10)=500$ years
Lithosphere: $\tau=2 \times 10^{9} / 10=2 \times 10^{8}$ years $=200$ million years.
2. Land reservoir $=$ Land biota + Land soil :
inventory $=1 \times 10^{4}+7 \times 10^{4}=8 \times 10^{4} \mathrm{Tg} \mathrm{N}$
flow out $=130+80+40=250 \mathrm{Tg} \mathrm{N} \mathrm{yr}^{-1}$
$\tau=8 \times 10^{4} / 250=320$ years
The residence time in the combined land reservoir is much longer than the residence time in either of the biota or soil reservoir because the rate of cycling between the land biota and land soil is much faster than the loss out of the combined reservoir.
3. When we add nitrogen to the land biota, it reaches a dynamic equilibrium with the land soil reservoir on a time scale $\tau_{\text {land biota }}=4$ years, which is much shorter than the 100 -year time scale we are asked to consider. By contrast, loss out of the combined land reservoir ( $\tau=320$ years) is slow relative to the 100year time scale; we can therefore consider that the added nitrogen has accumulated in the land reservoir over the past 100 years. The added nitrogen includes contributions from industrial fertilizer, nitrogenfixing crops, and fossil fuel combustion. All of the industrial fertilizer and nitrogen-fixing crops ( 130 Tg $\mathrm{N} \mathrm{yr}{ }^{-1}$ ) are applied to the land reservoir. However, only a fraction $f$ of the $25 \mathrm{Tg} \mathrm{N} \mathrm{yr}^{-1}$ fixed by fossil fuel combustion is deposited to land; the rest is deposited to the oceans. From the flow rates given in the diagram this fraction is $f=80 /(80+30)=0.7$. The accumulation of N in the land reservoir is therefore 130 $+(0.7 \times 25)=150 \mathrm{Tg} \mathrm{N} \mathrm{yr}^{-1}$, amounting to $1.5 \times 10^{4} \mathrm{Tg} \mathrm{N}$ over 100 years.

The present-day inventory of the land reservoir is $8 \times 10^{4} \mathrm{Tg} \mathrm{N}$; from the above we conclude that the inventory 100 years ago was $8-1.5=6.5 \times 10^{4} \mathrm{Tg} \mathrm{N}$. There has been a $23 \%$ increase in the size of the land reservoir over the past 100 years. Because of the rapid cycling between the land biota and the land soil, this percentage increase may be expected to apply to both biota and soil. This is a substantial global fertilization effect.

We apply the same reasoning to the ocean biota. On a time scale of 100 years, the ocean biota and deep ocean reservoirs are in dynamic equilibrium; the residence time of N in the sum of these two reservoirs (let's call it the "ocean reservoir") is $8 \times 10^{5} / 100=8,000$ years, much longer that our 100-year horizon. Over the past 100 years, fossil fuel combustion has added $100 \times(0.3 \times 25)=750 \mathrm{Tg} \mathrm{N}$ to the ocean reservoir; this amounts to only $750 / 8 \times 10^{5}=0.1 \%$ of the N inventory in that reservoir.

We conclude that there is potential for significant global fertilization of the land biosphere by human
activity but not of the ocean biosphere.

## 6. 6 Ocean pH

From the formulations of the equilibrium constants:

$$
\begin{aligned}
& K_{H}=\frac{\left[\mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}\right]}{P_{\mathrm{CO} 2}} \\
& K_{1}=\frac{\left[\mathrm{HCO}_{3}^{-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}\right]} \\
& K_{2}=\frac{\left[\mathrm{CO}_{3}^{2-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{HCO}_{3}^{-}\right]} \\
& K_{S}=\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{CO}_{3}^{2-}\right]
\end{aligned}
$$

we can express $\left[\mathrm{H}^{+}\right]$in terms of the input data to the problem:

$$
\left[H^{+}\right]=\left[\frac{K_{H} K_{1} K_{2}}{K_{S}}\left[\mathrm{Ca}^{2+}\right] P_{\mathrm{CO} 2}\right]^{\frac{1}{2}}
$$

Substituting numerical values we obtain an ocean $\mathrm{pH}=8.1$.

## 6. 7 Cycling of $\mathrm{CO}_{2}$ with the terrestrial biosphere

1. The total mass of carbon in the terrestrial vegetation reservoir is 730 Pg C . The total loss rate out of this reservoir is $62 \mathrm{Pg} \mathrm{C} \mathrm{yr}^{-1}$. Dividing the total mass by total loss rate, we find a lifetime of 12 years.
2. By comparing the different fluxes out of the litter reservoir, we see that the dominant fate of carbon in the litter is export to the atmosphere. Only $3 / 54=6 \%$ is incorporated into the soil.
3. Atmospheric $\mathrm{CO}_{2}$ would decrease if the source from microbial activity decreases, because more carbon could then be stored in the soil reservoir (which is larger than the atmospheric reservoir).

## 6. 8 Sink of atmospheric $\mathrm{CO}_{2}$ deduced from changes in atmospheric $\mathrm{O}_{2}$

1.1 The stoichiometric representation of fossil fuel combustion is

$$
\mathrm{CH}_{1.6}+1.4 \mathrm{O}_{2} \rightarrow \mathrm{CO}_{2}+0.8 \mathrm{H}_{2} \mathrm{O}
$$

Therefore, 1.4 moles of $\mathrm{O}_{2}$ are consumed per mole of $\mathrm{CO}_{2}$ emitted by fossil fuel combustion.
1.2 The stoichiometric representation of photosynthesis given in the chapter shows that one mole of $\mathrm{O}_{2}$ is produced per mole of $\mathrm{CO}_{2}$ taken up by the biosphere.
1.3 Oxygen is not involved in the dissolution and subsequent dissociation of $\mathrm{CO}_{2}$ in the ocean. There is no $\mathrm{O}_{2}$ produced or consumed when atmospheric $\mathrm{CO}_{2}$ is removed by this process.
2.1 Fossil fuel combustion over the 3-year period amounted to $3 \times 6.3 \times 10^{12}=18.9 \times 10^{12} \mathrm{~kg} \mathrm{C}=1.6 \times 10^{15}$ moles $\mathrm{CO}_{2}$. The total number of moles of air is $1.8 \times 10^{20}$ moles. Fossil fuel combustion would therefore have caused a 8.9 ppmv increase in $\mathrm{CO}_{2}$ and a $1.4 \times 8.9=12.4 \mathrm{ppmv}$ decrease in $\mathrm{O}_{2}$.
2.2 The observed decrease of $\mathrm{O}_{2}$ is 8.8 ppmv , less than the 12.4 ppmv predicted from fossil fuel combustion alone. The difference of 3.6 ppmv can be explained by uptake of $\mathrm{CO}_{2}$ by the biosphere. If we correct the predicted $\mathrm{CO}_{2}$ increase from fossil fuel combustion by this uptake, we find a net increase of $\mathrm{CO}_{2}$ of $8.9-3.6=5.3 \mathrm{ppmv}$. However, the observations show a $\mathrm{CO}_{2}$ increase of 3.2 ppmv . This means that 5.3-3.2 $=2.1 \mathrm{ppmv}$ of $\mathrm{CO}_{2}$ must have dissolved into the oceans. Therefore, of the $8.9 \mathrm{ppmv} \mathrm{CO}_{2}$ injected into the atmosphere by fossil fuel combustion, (a) 3.6 ppmv or $40 \%$ were taken up by the biosphere; (b) 2.1 ppmv or $24 \%$ dissolved in the ocean; (c) and 3.2 ppmv or $36 \%$ accumulated in the atmosphere.

## 5. Fossil fuel $\mathrm{CO}_{2}$ neutralization by marine $\mathrm{CaCO}_{3}$

1. Dissolution of $\mathrm{CaCO}_{3}$ provides a source of base $\left(\mathrm{CO}_{3}{ }^{2-}\right)$ to the ocean, facilitating uptake of $\mathrm{CO}_{2}(\mathrm{~g})$ following the equilibrium

$$
\mathrm{CO}_{2}(g)+\mathrm{CO}_{3}^{2-} \Leftrightarrow 2 \mathrm{HCO}_{3}^{-}
$$

2. Equilibrium between $\mathrm{CaCO}_{3}$ on the ocean floor and $\mathrm{CO}_{3}{ }^{2-}$ in the ocean is defined by

$$
\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{CO}_{3}^{2-}\right]=K_{s}
$$

If $\left[\mathrm{Ca}^{2+}\right]$ is constant then $\left[\mathrm{CO}_{3}{ }^{2-}\right]$ must also remain constant between the preindustrial and final states, since equilibrium is satisfied in both states.
3. The equilibrium

$$
\mathrm{CO}_{2}(g)+\mathrm{CO}_{3}^{2-} \Leftrightarrow 2 \mathrm{HCO}_{3}^{-}
$$

has an equilibrium constant

$$
\frac{\left[\mathrm{HCO}_{3}^{-}\right]^{2}}{P_{\mathrm{CO} 2}\left[\mathrm{CO}_{3}^{2-}\right]}=\frac{K_{H} K_{1}}{K_{2}}
$$

Therefore,

$$
\left\{\frac{\left[\mathrm{HCO}_{3}^{-}\right]^{2}}{P_{\mathrm{CO} 2}\left[\mathrm{CO}_{3}^{2-}\right]}\right\}_{\text {preindustrial }}=\left\{\frac{\left[\mathrm{HCO}_{3}^{-}\right]^{2}}{P_{\mathrm{CO} 2}\left[\mathrm{CO}_{3}^{2-}\right]}\right\}_{\text {final }}
$$

and since $\left[\mathrm{CO}_{3}{ }^{2-}\right]_{\text {final }}=\left[\mathrm{CO}_{3}{ }^{2-}\right]_{\text {preindustrial, }}$ we have the desired relationship:

$$
\frac{P_{\mathrm{CO2,} \mathrm{final}}}{P_{\mathrm{CO} 2, \text { preindustrial }}}=\left(\frac{\left[\mathrm{HCO}_{3}^{-}\right]_{\text {final }}}{\left[\mathrm{HCO}_{3}^{-}\right]_{\text {preindustrial }}}\right)^{2}
$$

4. $\mathrm{CO}_{2}(\mathrm{~g})$ enters the ocean by

$$
. \mathrm{CO}_{2}(g)+\mathrm{CO}_{3}^{2-} \Leftrightarrow 2 \mathrm{HCO}_{3}^{-}
$$

which consumes $\mathrm{CO}_{3}{ }^{2-}$ from the ocean. Since the ocean $\mathrm{CO}_{3}{ }^{2-}$ concentration in the final state is the same as in the initial state, $\mathrm{CO}_{3}{ }^{2-}$ must be replenished by dissolution of $\mathrm{CaCO}_{3}$ from the ocean floor. From the above equilibrium, we see that every molecule of $\mathrm{CO}_{2}(\mathrm{~g})$ entering the ocean adds two $\mathrm{HCO}_{3}{ }^{-}$molecules to the ocean (one originating from the dissolution of $\mathrm{CO}_{2}(\mathrm{~g})$, the other one from dissolution of $\mathrm{CaCO}_{3}$ ). If we emit to the atmosphere all the identified fossil fuel reserves ( $5 \times 10^{18} \mathrm{~g} \mathrm{C}$ ), and all of this carbon enters the ocean, the mass of $\mathrm{HCO}_{3}{ }^{-}$in the ocean will increase by $10 \times 10^{18} \mathrm{~g} \mathrm{C}$.
5. Substituting the above result in the equation of question 3:

$$
\frac{P_{\mathrm{CO2,final}}}{P_{\mathrm{CO2} \text {,preindustrial }}}=\left(\frac{\left[\mathrm{HCO}_{3}^{-}\right]_{\text {final }}}{\left[\mathrm{HCO}_{3}{ }^{-}\right]_{\text {preindustrial }}}\right)^{2}=\left(\frac{38+10}{38}\right)^{2}=1.60
$$

With $P_{\text {CO2,preindustrial }}=280 \mathrm{ppmv}$ we find $P_{\text {CO2,final }}=450 \mathrm{ppmv}$. The difference, 170 ppmv , corresponds to a carbon mass of $170 \times 10^{-6} \times 1.8 \times 10^{20} \times 12=3.6 \times 10^{17} \mathrm{~g} \mathrm{C}$ remaining in the atmosphere. Comparing to the total fossil fuel carbon emitted ( $5 \times 10^{18} \mathrm{~g} \mathrm{C}$ ), we conclude that $3.6 \times 10^{17} / 5 \times 10^{18}=7 \%$ of the emitted $\mathrm{CO}_{2}$ remains in the atmosphere. This is substantially less than the $28 \%$ fraction calculated without accounting for $\mathrm{CaCO}_{3}$ dissolution!

## SOLUTIONS TO PROBLEMS, CHAPTER 7

## 7. 1 Climate response to changes in ozone

1. Ozone is a major source of heat in the stratosphere. Removing all ozone above 30 km will therefore result in a large stratospheric cooling. It will also allow more UV radiation to penetrate to the troposphere, resulting in tropospheric warming.
2. Ozone is a far more effective greenhouse gas in the upper troposphere than in the lower troposphere because of the decrease of temperature with altitude. Radiation emitted by the Earth's surface and absorbed by ozone in the upper troposphere is reemitted at a much lower temperature, reducing the radiation flux escaping to space and therefore warming the Earth's surface. In contrast, radiation absorbed by ozone near the surface is reemitted at nearly the same temperature as the surface, so that the greenhouse effect is minimal.

## 7. 2 Interpretation of the terrestrial radiation spectrum

1. The radiation flux measured in the atmospheric window ( $8-12 \mu \mathrm{~m}$, or $800-1250 \mathrm{~cm}^{-1}$ ), where absorption by the atmosphere is minimal, represents blackbody emission from the Earth's surface. The corresponding surface temperatures are 320 K (Sahara), 280 K (Mediterranean), and 180 K (Antarctica).
2. The dips at $600-700 \mathrm{~cm}^{-1}(14-16 \mu \mathrm{~m})$ and $1000-1050 \mathrm{~cm}^{-1}(9.5-10 \mu \mathrm{~m})$ in the emission spectra for the Sahara and Mediterranean Sea are due to atmospheric absorption and reemission by $\mathrm{CO}_{2}$ and $\mathrm{O}_{3}$, respectively. The corresponding temperatures of $220 \mathrm{~K}\left(600-700 \mathrm{~cm}^{-1}\right)$ and $250-280 \mathrm{~K}\left(1000-1050 \mathrm{~cm}^{-1}\right)$ represent the "tops" of the atmospheric columns, roughly the tropopause for $\mathrm{CO}_{2}$ and the upper stratosphere for $\mathrm{O}_{3}$. These dips become bumps in the emission spectrum over Antarctica because the surface there is colder than the atmosphere overhead.

### 7.3 Jupiter and Mars

1.1 Calculate the effective temperature $T_{J}$ of Jupiter assuming that the Sun is the only energy source:

$$
T_{J}=\left[\frac{F_{S}(1-A)}{4 \sigma}\right]^{\frac{1}{4}}=\left[\frac{\sigma T_{S}^{4}\left(\frac{R_{S}}{d}\right)^{2}(1-A)}{4 \sigma}\right]^{\frac{1}{4}}=T_{S}\left(\frac{R_{S}}{d}\right)^{\frac{1}{2}}\left(\frac{1-A}{4}\right)^{\frac{1}{4}}
$$

Substituting numerical values we find $\mathrm{T}_{\mathrm{J}}=89 \mathrm{~K}$.
1.3 Let $H$ be the internal energy source per unit area of Jupiter's surface. We write an energy balance equation for the planet:

$$
H+\frac{F_{S}(1-A)}{4}=\sigma T_{J}^{4}
$$

From question 1.1, $F_{S}(1-A) / 4=\sigma T_{\mathrm{J}, \mathrm{o}}^{4}$ where $T_{J, o}=89 \mathrm{~K}$ is the effective temperature of Jupiter computed without the internal energy source. Therefore,

$$
H=\sigma\left(T_{J}^{4}-T_{J, o}^{4}\right)
$$

The ratio $R$ of the internal energy source to the energy received from the Sun is

$$
R=\frac{H}{\frac{F_{S}(1-A)}{4}}=\frac{T_{J}^{4}-T_{J, o}^{4}}{T_{J, o}^{4}}=\left(\frac{T_{J}}{T_{J, o}}\right)^{4}-1=\left(\frac{134}{89}\right)^{4}-1=4.1
$$

Jupiter's temperature is therefore maintained principally by internal sources of heat.
2.1 Effective temperature of Mars:

$$
T_{M}=T_{S}\left(\frac{R_{S}}{d}\right)^{\frac{1}{2}}\left(\frac{1-A}{4}\right)^{\frac{1}{4}}=218 K
$$

2.2 The observed surface temperature of Mars, 220 K , is only 2 K higher than the effective temperature. We conclude that the atmosphere on Mars provides only a small greenhouse effect, much smaller than on Earth where the difference between surface and effective temperatures is $288-255=33 \mathrm{~K}$.

## 7. 4 The "faint Sun" problem

1. From our simple greenhouse model:

$$
T_{o}=\left[\frac{F_{S}(1-A)}{4 \sigma\left(1-\frac{f}{2}\right)}\right]^{\frac{1}{4}}
$$

The present-day solar constant $F_{S}$ is $1370 \mathrm{~W} \mathrm{~m}^{-2} ; 3.8$ billion years ago it was $0.75 \times 1370=1030 \mathrm{~W} \mathrm{~m}^{-2}$. Replacing in the above equation, and assuming the same albedo $(A)$ and atmospheric composition (f) as today, we obtain:

$$
T_{o}=\left[\frac{1030 \times(1-0.28)}{4 \times 5.7 \times 10^{-8} \times\left(1-\frac{0.77}{2}\right)}\right]^{\frac{1}{4}}=270 \mathrm{~K}
$$

which is too cold for liquid water to be present.
2. $100 \%$ absorption of terrestrial radiation is represented in our simple model by $f=1$. Replacing in the above equation, with other numerical values the same, we obtain $T_{o}=284 \mathrm{~K}$. This is sufficient to maintain liquid water.
3. In a thick greenhouse atmosphere, radiation emitted by the atmosphere is reabsorbed by the atmosphere above it. We can represent this situation in our simple greenhouse model by considering two superimposed atmospheric layers, each absorbing $100 \%$ of terrestrial/atmospheric radiation:

The energy balance equation for the (Earth + atmosphere ) system is

$$
\begin{equation*}
\frac{F_{S}(1-A)}{4}=\sigma T_{2}^{4} \tag{1}
\end{equation*}
$$

The energy balance equation for atmospheric layer 2 is

$$
\begin{equation*}
\sigma T_{1}^{4}=2 \sigma T_{2}^{4} \tag{2}
\end{equation*}
$$

The energy balance equation for atmospheric layer 1 is

$$
\begin{equation*}
\sigma T_{o}^{4}+\sigma T_{2}^{4}=2 \sigma T_{1}^{4} \tag{3}
\end{equation*}
$$

From equations (2) and (3) we obtain

$$
\sigma T_{o}^{4}=3 \sigma T_{2}^{4}
$$

and replacing into (1):

$$
T_{o}=\left[\frac{3 F_{S}(1-A)}{4 \sigma}\right]^{\frac{1}{4}}
$$

Substituting numerical values we obtain $T_{o}=314 \mathrm{~K}$ (warm!). We see how a thick greenhouse atmosphere can compensate for a weaker Sun.
4. In the present Earth, atmospheric $\mathrm{CO}_{2}$ is taken up by the oceans and by the biosphere. In an Earth covered with ice these sinks would not operate. Therefore $\mathrm{CO}_{2}$ would accumulate in the atmosphere.

## 7. 5 Planetary skin

For the "thin" atmospheric layer, $f^{\prime} \ll 1 \Rightarrow\left(1-f^{\prime}\right) \approx 1$. We use this approximation in what follows. The radiative flux balance equation for the (Earth + atmosphere) system is given by

$$
\begin{equation*}
F_{s} \frac{(1-A)}{4}=(1-f) \sigma T_{o}^{4}+f \sigma T_{\text {main }}^{4}+f^{\prime} \sigma T_{\text {thin }}^{4} \tag{1}
\end{equation*}
$$

and the radiative flux balance equation for the thin atmospheric layer is given by

$$
\begin{equation*}
f^{\prime}\left[(1-f) \sigma T_{o}^{4}+f \sigma T_{\text {main }}^{4}\right]=2 f^{\prime} \sigma T_{\text {thin }}^{4} \tag{2}
\end{equation*}
$$

Replacing (2) into (1):

$$
F_{s} \frac{(1-A)}{4}=2 \sigma T_{t h i n}^{4}+f^{\prime} \sigma T_{\text {thin }}^{4}=\sigma T_{\text {thin }}^{4}\left(2+f^{\prime}\right)=2 \sigma T_{\text {thin }}^{4}
$$

Substituting numerical values $\left(F_{S}=1370 \mathrm{~W} \mathrm{~m}^{-2}, A=0.28, \sigma=5.7 \times 10^{-8} \mathrm{~W} \mathrm{~m}^{-2}{ }^{\mathrm{o}} \mathrm{K}^{-4}\right.$ ) we obtain $T_{\text {thin }}=217$ K. In an atmosphere that doesn't absorb solar radiation this is the coldest temperature that can be achieved, corresponding to heating from below but no heating from above. Indeed, this "skin" temperature corresponds roughly to the range of temperatures observed near the tropopause. At higher altitudes, absorption of solar radiation by the stratospheric ozone layer provides a local source of heat.

## 7. 6 Absorption in the atmospheric window

1. The water vapor dimer is in equilibrium with water vapor,

$$
\mathrm{H}_{2} \mathrm{O}+\mathrm{H}_{2} \mathrm{O} \Leftrightarrow\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}
$$

with an equlibrium constant $K=\left[\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right] /\left[\mathrm{H}_{2} \mathrm{O}\right]^{2}$. The absorption coefficient from the water vapor dimer is proportional to the dimer column concentration, which in turn is proportional (from the equilibrium constant) to the square of the water vapor concentration. So $k \sim p^{2}$.
2. The optical depth $\mathrm{d} \delta$ from absorption by the water vapor dimer in an elemental horizontal slab of
thickness $d z$ is given by

$$
d \delta=k \rho d z
$$

where $k$ is the absorption coefficient given in units of $\mathrm{m}^{2}$ per kg of air, and $\rho$ is the mass density of air ( kg $\mathrm{m}^{-3}$ ). We have $k=\alpha p^{2}$ where $\alpha=1 \times 10^{-11} \mathrm{~m}^{2} \mathrm{~kg}^{-1} \mathrm{~Pa}^{-2}$. Let $C$ denote the mixing ratio of water vapor, $h=4$ km the corresponding scale height, $P$ the atmospheric pressure, and $P_{o}$ the atmospheric pressure at sea level:

$$
p=C P=C_{o} P_{o} \exp \left[-z\left(\frac{1}{h}+\frac{1}{H}\right)\right]=p_{o} \exp \left[-z\left(\frac{1}{h}+\frac{1}{H}\right)\right]
$$

We therefore have:

$$
d \delta=k \rho_{a} d z=\alpha\left(p_{o}^{2} \exp \left[-2 z\left(\frac{1}{h}+\frac{1}{H}\right)\right]\right) \rho_{o} \exp \left[-\frac{z}{H}\right] d z=\alpha \rho_{o} p_{o}^{2} \exp \left[-z\left(\frac{2}{h}+\frac{3}{H}\right)\right] d z
$$

We now integrate over the depth of the atmosphere to obtain the total optical depth $\delta$ :

$$
\delta=\int d \delta=\int_{0}^{\infty} \alpha \rho_{o} p_{o}^{2} \exp \left[-z\left(\frac{2}{h}+\frac{3}{H}\right)\right] d z=\frac{\alpha \rho_{o} p_{o}^{2}}{\left(\frac{2}{h}+\frac{3}{H}\right)}=\frac{1 \times 10^{-11} \cdot 1.2 \cdot 1 \times 10^{6}}{\frac{2}{4 \times 10^{3}}+\frac{3}{7.4 \times 10^{3}}}=0.013
$$

The water vapor dimer absorbs only $1.3 \%$ of the incoming radiation; it is not an efficient absorber.

## SOLUTIONS TO PROBLEMS, CHAPTER 8

## 8. 1 Lifetime of aerosols

1. At steady state, the loss rate $L$ of ${ }^{210} \mathrm{~Pb}$ from deposition balances the ${ }^{222} \mathrm{Rn}$ emission rate, which is 1.0 atoms $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ over $30 \%$ of the Earth's surface area $4 \pi R^{2}=5.1 \times 10^{8} \mathrm{~km}^{2}$ :
$L=1.0 \times 0.3 \times 5.1 \times 10^{18}=1.5 \times 10^{18}$ atoms s $^{-1}$
The mass of ${ }^{210} \mathrm{~Pb}$ in the troposphere is $380 \mathrm{~g}=(380 / 210) \times 6.023 \times 10^{23}=1.09 \times 10^{24}$ atoms
Therefore the residence time of ${ }^{210} \mathrm{~Pb}$-carrying aerosols in the troposphere is $1.09 \times 10^{24} / 1.5 \times 10^{18}=7.3 \times 10^{5}$ $\mathrm{s}=8.4$ days.
2. We write the steady-state mass balance equations for ${ }^{7} \mathrm{Be}$ in the stratosphere $\left(m_{S}\right)$ and in the troposphere $\left(m_{T}\right)$ :

$$
\begin{gathered}
P_{S}=\left(k_{c}+k_{S T}\right) m_{S} \\
P_{T}+k_{S T} m_{S}=\left(k_{c}+k_{d}\right) m_{T}
\end{gathered}
$$

where $P_{S}$ and $P_{T}$ are the production rates of ${ }^{7} \mathrm{Be}$ in the stratosphere and troposphere, respectively; $k_{c}=4.7$ $\mathrm{yr}^{-1}$ is the rate constant for radioactive decay; and $k_{d}$ is the unknown rate constant for deposition in the troposphere. We have neglected the transfer of ${ }^{7} \mathrm{Be}$ from the troposphere to the stratosphere, which must be negligibly small in view of the short lifetimes of tropospheric ${ }^{7}$ Be against radioactive decay and deposition. From the two equations we derive an expression for $k_{d}$,

$$
\begin{gathered}
k_{d}=\frac{P_{T}+\frac{k_{S T}}{k_{c}+k_{S T}} P_{S}}{m_{T}}-k_{c} \\
=\frac{0.3 \cdot 150+\frac{0.8}{4.7+0.8} \cdot 0.7 \cdot 150}{3}-4.7=15.3 \mathrm{yr}^{-1}
\end{gathered}
$$

so that the lifetime against deposition of ${ }^{7}$ Be-carrying aerosols in the troposphere is $1 / k_{d}=24$ days.
3. The large difference in lifetimes between ${ }^{210} \mathrm{~Pb}$-carrying and ${ }^{7} \mathrm{Be}$-carrying aerosols in the troposphere reflects differences in the vertical distributions of the sources. The source of ${ }^{210} \mathrm{~Pb}$ is mostly in the lower troposphere, while the source of ${ }^{7} \mathrm{Be}$ is mostly in the upper troposphere. It rains far less frequently in the upper troposphere than in the lower troposphere and therefore the lifetime of ${ }^{7}$ Be-carrying aerosols is longer than that of ${ }^{210} \mathrm{~Pb}$-carrying aerosols. The time scale for vertical mixing in the troposphere ( $\sim 1$ month) is sufficiently long compared to the aerosol lifetimes that the vertical gradients in aerosol concentrations will be maintained.
4. The higher concentration of ${ }^{210} \mathrm{~Pb}$ in the stratosphere results from the lack of a rainout sink in the stratosphere. It also means that the air entering the stratosphere must be relatively rich in ${ }^{222} \mathrm{Rn}$, as would be expected if deep convection in the tropics is an important mechanism for transport from the troposphere to the stratosphere.

## 8. 2 Aerosols and radiation

1. An increase in sulfate aerosol concentrations would cause a decrease of $T_{o}$ as less solar radiation would reach the Earth's surface (i.e., the albedo would increase).
2. The effect of the soot layer depends on its altitude. A soot layer near the surface effectively decreases the albedo of the surface (think for example of a soot layer above a snow surface) so that $T_{o}$ will increase. A soot layer in the upper troposphere has a more complicated effect. On the one hand it absorbs solar radiation and reemits half of it back to space, preventing it from reaching the surface; on the other hand it absorbs terrestrial radiation and reemits half to the Earth, warming the surface.
3. Start from the radiative balance equation:

$$
\frac{S(1-A)}{4}=\left(1-\frac{f}{2}\right) \sigma T_{o}^{4}
$$

Differentiate both sides, with $\varepsilon=d A$ and $\varepsilon^{\prime}=d f$ :

$$
-\frac{S \varepsilon}{4}=4 \sigma T_{o}^{3}\left(1-\frac{f}{2}\right) d T_{o}-\frac{\varepsilon^{\prime}}{2} \sigma T_{o}^{4}
$$

Rearrange:

$$
\frac{\varepsilon^{\prime}}{2} \sigma T_{o}^{4}-\frac{S \varepsilon}{4}=4 \sigma T_{o}^{3}\left(1-\frac{f}{2}\right) d T_{o}
$$

In order that $d T_{o}$ be greater than 0 , we must have

$$
\frac{\varepsilon^{\prime}}{2} \sigma T_{o}^{4}>\frac{S \varepsilon}{4}
$$

which by rearrangement gives

$$
\frac{\varepsilon^{\prime}}{\varepsilon}>\frac{S}{2 \sigma T_{o}^{4}} \approx 1.8
$$

## SOLUTIONS TO PROBLEMS, CHAPTER 10

## 10. 1 Shape of the ozone layer

1. Let $k(z)=q \sigma I(z)$ represent the $\mathrm{O}_{2}$ photolysis rate constant at altitude $z$ :

$$
R(z)=k\left[O_{2}\right]=q \sigma I C_{O 2} n_{a}(0) \exp \left[-\frac{z}{H}\right]
$$

The actinic flux $I(z)$ is attenuated from the radiation flux $I_{\infty}$ at the top of the atmosphere by the $\mathrm{O}_{2}$ column overhead:

$$
I(z)=I_{\infty} \exp \left[-\sigma \int_{z}^{\infty}\left[O_{2}\right] d z^{\prime}\right]
$$

We substitute for $\left[\mathrm{O}_{2}\right]$ and integrate:

$$
\begin{aligned}
I(z) & =I_{\infty} \exp \left[-\sigma C_{O 2} n_{a}(0) \int_{z}^{\infty} e^{-z^{\prime} / H} d z^{\prime}\right] \\
& =F_{\infty} \exp \left[-H \sigma C_{O 2} n_{a}(0) e^{-z / H}\right]
\end{aligned}
$$

Replace into the equation for $R(z)$ :

$$
R(z)=q \sigma C_{O 2} n_{a}(0) I_{\infty} \exp \left[-\frac{z}{H}-H \sigma C_{O 2} n_{a}(0) e^{-z / H}\right]
$$

2) What is the shape of $R(z)$ ? We first remark that $R(z)$ is positive throughout the atmosphere and that $R(\infty)$ $\rightarrow 0$. Is there a maximum for $R(z)$ ? We examine the derivative:

$$
\frac{d R(z)}{d z}=q \sigma C_{O 2} n_{a}(0) I_{\infty}\left(-\frac{1}{H}+\sigma C_{O 2} n_{a}(0) e^{-z / H}\right) \exp \left[-\frac{z}{H}-H \sigma C_{O 2} n_{a}(0) e^{-z / H}\right]
$$

An extremum requires $d R / d z=0$, i.e.,

$$
-\frac{1}{H}+\sigma C_{O 2} n_{a}(0) e^{-z / H}=0
$$

which does have a positive solution:

$$
z_{\max }=H \ln \left(\sigma C_{O 2} H n_{a}(0)\right)
$$

From this information we sketch $R(z)$ vs. $z$ :

which represents qualitatively the shape of the ozone layer. $R(z)$ is the $\mathrm{O}_{\mathrm{x}}$ production rate. The $\mathrm{O}_{2}$ number density decreases with altitude and tends to zero towards the top of the atmosphere, while the $\mathrm{O}_{2}$ photolysis rate constant $k$ decreases as you penetrate down into the atmosphere and tends to zero near the surface. Therefore the product of the two must show a maximum somewhere in the atmospheric column, corresponding to the region of maximum $\mathrm{O}_{\mathrm{x}}$ production.

### 10.2 Chapman mechanism

1. 

Lifetime of the O atom:

$$
\tau_{o}=\frac{[O]}{k_{2}[O]\left[O_{2}\right][M]}=\frac{1}{k_{2} C_{O_{2}} n_{a}^{2}(z)}
$$

Substituting numerical values, we obtain $\tau_{\mathrm{O}}=1.5 \times 10^{-3} \mathrm{~s}$ at 20 km and $\tau_{\mathrm{O}}=2.8 \mathrm{~s}$ at 45 km . The oxygen atom can be assumed to be in chemical steady state throughout the stratosphere because its chemical lifetime is so short relative to the time scales for transport.
2. $[\mathrm{O}] /\left[\mathrm{O}_{3}\right]$ is defined by the fast cycling reactions $2 \& 3$.

$$
\begin{gathered}
k_{2}[O]\left[O_{2}\right][M]=k_{3}\left[O_{3}\right] \\
\frac{[O]}{\left[O_{3}\right]}=\frac{k_{3}}{k_{2}\left[O_{2}\right][M]}=\frac{k_{3}}{k_{2} C_{O_{2}}^{n_{a}^{2}(z)}}
\end{gathered}
$$

@ 20 km :

$$
\frac{[O]}{\left[O_{3}\right]}=1.5 \times 10^{-5} \mathrm{~mol} / \mathrm{mol}
$$

@ 45 km :

$$
\frac{[O]}{\left[O_{3}\right]}=0.028 \mathrm{~mol} / \mathrm{mol}
$$

Yes, we can assume $\left[\mathrm{O}_{3}\right]=\left[\mathrm{O}_{\mathrm{x}}\right]$ throughout the stratosphere.
3. $\mathrm{O}_{\mathrm{x}}$ production $=$ reaction $1(\mathrm{x} 2)$
$\mathrm{O}_{\mathrm{x}}$ loss $=$ reaction $4(\mathrm{x} 2)$
Mass balance equation for $\mathrm{O}_{\mathrm{x}}$ :

$$
\frac{d\left[O_{x}\right]}{d t}=2 k_{1}\left[O_{2}\right]-2 k_{4}\left[O_{3}\right][O]
$$

The first term on the right hand side is the $O_{x}$ production rate, and the second term contains an [O] which can be substituted for using the ratio derived in part 2 of this problem:

$$
\frac{d\left[O_{x}\right]}{d t}=P-2 k_{4}\left[O_{3}\right]\left(\frac{k_{3}\left[O_{3}\right]}{k_{2} C_{O_{2}}^{n}{ }_{a}^{2}(z)}\right)
$$

Also, from part 2, $\left[\mathrm{O}_{3}\right] \approx\left[\mathrm{O}_{\mathrm{x}}\right]$; therefore,

$$
\frac{d\left[O_{x}\right]}{d t}=P-k\left[O_{x}\right]^{2}
$$

where

$$
k=\frac{2 k_{4} k_{3}}{k_{2} C_{O_{2}} n_{a}^{2}(z)}
$$

4. 

$$
\tau_{O_{x}}=\frac{\left[O_{x}\right]}{\operatorname{loss}\left(O_{x}\right)}=\frac{\left[O_{x}\right]}{k\left[O_{x}\right]^{2}}=\frac{1}{k\left[O_{x}\right]}
$$

$\mathrm{k}(20 \mathrm{~km})=$

$$
\begin{gathered}
\frac{2\left(1 \times 10^{-2}\right)\left(8 \times 10^{-12}\right)\left(\exp \left(-\frac{2060}{200}\right)\right)}{\left(1 \times 10^{-33}\right)(0.21)\left(1.8 \times 10^{18}\right)^{2}}=7.9 \times 10^{-21}\left(\frac{\mathrm{~cm}^{3}}{\text { molec } s}\right) \\
{\left[O_{x}\right] \cong\left[O_{3}\right]=2 \times 10^{12}\left(\frac{\text { molec }}{\mathrm{cm}^{3}}\right)} \\
\tau_{O x}=\frac{1}{\left(7.9 \times 10^{-21}\right)\left(2 \times 10^{12}\right)}=2 \text { years }
\end{gathered}
$$

$\mathrm{k}(45 \mathrm{~km})=$

$$
\begin{gathered}
\frac{2\left(1 \times 10^{-2}\right)\left(8 \times 10^{-12}\right)\left(\exp \left(-\frac{2060}{270}\right)\right)}{\left(1 \times 10^{-33}\right)(0.21)\left(4.1 \times 10^{16}\right)^{2}}=2.2 \times 10^{-16}\left(\frac{\mathrm{~cm}^{3}}{\text { molec } s}\right) \\
{\left[O_{x}\right] \cong\left[O_{3}\right]=0.2 \times 10^{12}\left(\frac{\text { molec }}{\mathrm{cm}^{3}}\right)} \\
\tau_{O x}=6 \text { hours }
\end{gathered}
$$

5. Chemical steady state for $\mathrm{O}_{\mathrm{x}}$ should apply in the upper but not in the lower stratosphere. Therefore, the upper stratosphere is best for testing the Chapman mechanism by comparing observed $\mathrm{O}_{3}$ concentrations to those predicted from chemical steady state.

### 10.3 The detailed Chapman mechanism

1.1 Loss of $\mathrm{O}\left({ }^{1} \mathrm{D}\right)$ is by reactions (5) and (6),

$$
\begin{gathered}
\tau_{O\left({ }^{1} D\right)}=\frac{\left[O\left({ }^{1} D\right)\right]}{k_{5}\left[O\left({ }^{1} D\right)\right]\left[N_{2}\right]+k_{6}\left[O\left({ }^{1} D\right)\right]\left[O_{2}\right]}=\frac{1}{k_{5}\left[N_{2}\right]+k_{6}\left[O_{2}\right]} \\
=\frac{1}{\left(k_{5} C_{N 2}+k_{6} C_{O 2}\right) n_{a}}=6.6 \times 10^{-7} \mathrm{~s}
\end{gathered}
$$

Steady-state for $\mathrm{O}\left({ }^{1} \mathrm{D}\right)$ : production by reaction (3) must balance loss by reactions (5) and (6),

$$
k_{3}\left[O_{3}\right]=k_{5}\left[O\left({ }^{1} D\right)\right]\left[N_{2}\right]+k_{6}\left[O\left({ }^{1} D\right)\right]\left[O_{2}\right]=\frac{\left[O\left({ }^{1} D\right)\right]}{\tau_{O\left({ }^{1} D\right)}}
$$

so that

$$
\left[O\left({ }^{1} D\right)\right]=\tau_{O\left({ }^{( } D\right)} k_{3}\left[O_{3}\right]=5.4 \times 10^{2} \text { molecules } \mathrm{cm}^{-3}
$$

1.2 Loss of $\mathrm{O}\left({ }^{3} \mathrm{P}\right)$ is by reactions (4) and (7), with rate(4) >> rate (7):

$$
\tau_{O\left({ }^{3} P\right)}=\frac{1}{k_{4}\left[O_{2}\right][M]+k_{7}\left[O_{3}\right]} \approx \frac{1}{k_{4}\left[O_{2}\right][M]}=\frac{1}{k_{4} C_{O 2} n_{a}^{2}}=2.3 \mathrm{~s}
$$

Steady-state for $\mathrm{O}\left({ }^{3} \mathrm{P}\right)$ : production by reactions (1), (2), (5), (6) must balance loss by reactions (4) and (7). Two simplifications can be made:

- rate(1) and rate(7) (production and loss of $\mathrm{O}_{\mathrm{x}}$ ) are small compared to the other terms (cycling of $\mathrm{O}_{\mathrm{x}}$ )
- $\quad$ rate(5)+rate(6)=rate(3) (steady state for $\mathrm{O}\left({ }^{1} \mathrm{D}\right)$ )

$$
\left(k_{2}+k_{3}\right)\left[O_{3}\right]=k_{4}\left[O\left(^{3} P\right)\right]\left[O_{2}\right][M]
$$

so that

$$
\left[O\left({ }^{3} P\right)\right]=\frac{k_{2}+k_{3}}{k_{4}} \frac{\left[O_{3}\right]}{C_{O 2} n_{a}^{2}}=2.4 \times 10^{9} \text { molecules } \mathrm{cm}^{-3}
$$

1.3 Calculate the lifetime of $\mathrm{O}_{\mathrm{x}}$. Loss of $\mathrm{O}_{\mathrm{x}}$ is by reaction (7), which consumes two $\mathrm{O}_{\mathrm{x}}$ molecules, and $\left[\mathrm{O}_{\mathrm{x}}\right]$ $\approx\left[\mathrm{O}_{3}\right]$ :

$$
\tau_{O_{x}}=\frac{1}{2 k_{7}\left[O\left({ }^{3} P\right)\right]}=18 \text { hours }
$$

2. If $\mathrm{O}_{\mathrm{x}}$ is in steady state (a reasonable assumption in view of the short lifetime calculated above), its total loss $L_{O x}$ must balance its production $P_{O x}$ from reaction (1):

$$
L_{O x}=P_{O x}=2 k_{1}\left[O_{2}\right]
$$

The loss from the Chapman mechanism by reaction (7) accounts for a fraction

$$
\frac{2 k_{7}\left[O\left({ }^{3} P\right)\right]\left[O_{3}\right]}{2 k_{1}\left[O_{2}\right]}=24 \% \text { of the total } \mathrm{O}_{x} \text { loss }
$$

There must be therefore other sinks for $\mathrm{O}_{\mathrm{x}}$ than the Chapman mechanism.

## 10. $4 \mathrm{HO}_{x}$-catalyzed ozone loss

$\left(\mathrm{HO}_{x}=\mathrm{H}, \mathrm{OH}, \mathrm{HO}_{2}\right)$

1. Catalytic $\mathrm{O}_{3}$ loss cycles starting with reaction of OH :
a)

$$
\begin{align*}
& \mathrm{OH}+\mathrm{O}_{3} \rightarrow \mathrm{HO}_{2}+\mathrm{O}_{2}  \tag{3}\\
& \mathrm{HO}_{2}+\mathrm{O} \rightarrow \mathrm{OH}+\mathrm{O}_{2} \tag{6}
\end{align*}
$$

Net: $\mathrm{O}+\mathrm{O}_{3} \rightarrow 2 \mathrm{O}_{2}$
b)

$$
\begin{gather*}
\mathrm{OH}+\mathrm{O}_{3} \rightarrow \mathrm{HO}_{2}+\mathrm{O}_{2}  \tag{3}\\
\mathrm{HO}_{2}+\mathrm{O}_{3} \rightarrow \mathrm{OH}+2 \mathrm{O}_{2} \tag{7}
\end{gather*}
$$

Net: $2 \mathrm{O}_{3} \rightarrow 3 \mathrm{O}_{2}$
c)

$$
\begin{gather*}
\mathrm{OH}+\mathrm{O} \rightarrow \mathrm{O}_{2}+\mathrm{H}  \tag{1}\\
\mathrm{H}+\mathrm{O}_{3} \rightarrow \mathrm{O}_{2}+\mathrm{OH}  \tag{5}\\
\text { Net: } \mathrm{O}+\mathrm{O}_{3} \rightarrow 2 \mathrm{O}_{2}
\end{gather*}
$$

d)

$$
\begin{gathered}
\mathrm{OH}+\mathrm{O} \rightarrow \mathrm{O}_{2}+\mathrm{H} \\
\mathrm{H}+\mathrm{O}_{2}+\mathrm{M} \rightarrow \mathrm{HO}_{2}+\mathrm{M} \\
\mathrm{HO}_{2}+\mathrm{O}_{3} \rightarrow \mathrm{OH}+2 \mathrm{O}_{2}
\end{gathered}
$$

$$
\text { Net: } \mathrm{O}+\mathrm{O}_{3} \rightarrow 2 \mathrm{O}_{2}
$$

e)

$$
\begin{gather*}
\mathrm{OH}+\mathrm{O} \rightarrow \mathrm{O}_{2}+\mathrm{H}  \tag{1}\\
\mathrm{H}+\mathrm{O}_{2}+\mathrm{M} \rightarrow \mathrm{HO}_{2}+\mathrm{M}  \tag{4}\\
\mathrm{HO}_{2}+\mathrm{O} \rightarrow \mathrm{OH}+\mathrm{O}_{2} \tag{6}
\end{gather*}
$$

Net: $\mathrm{O}+\mathrm{O} \rightarrow \mathrm{O}_{2}$
2) The sinks for $\mathrm{HO}_{x}$ are

$$
\begin{gather*}
\mathrm{OH}+\mathrm{HO}_{2} \rightarrow \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2}  \tag{2}\\
\mathrm{HO}_{2}+\mathrm{HO}_{2} \rightarrow \mathrm{H}_{2} \mathrm{O}_{2}+\mathrm{O}_{2} \tag{8}
\end{gather*}
$$

## 10. 5 Chlorine chemistry at mid-latitudes

1. 

$$
{ }^{\tau} \mathrm{Cl}=\frac{[\mathrm{Cl}]}{[\mathrm{Cl}]\left(k_{1}\left[\mathrm{O}_{3}\right]+k_{2}\left[\mathrm{CH}_{4}\right]\right)}=\frac{1}{k_{1}\left[\mathrm{O}_{3}\right]+k_{2}\left[\mathrm{CH}_{4}\right]}=3.5 \times 10^{-2} \mathrm{~s}
$$

$k_{1}\left[\mathrm{O}_{3}\right] \gg k_{2}\left[\mathrm{CH}_{4}\right]$, so the principal sink for Cl is reaction with $\mathrm{O}_{3}$.

$$
\begin{gathered}
\tau_{\mathrm{ClO}}=\frac{[\mathrm{ClO}]}{[\mathrm{ClO}]\left(k_{3}[\mathrm{O}]+k_{5}[\mathrm{NO}]+k_{6}\left[\mathrm{HO}_{2}\right]+k_{7}\left[\mathrm{NO}_{2}\right]\right)}= \\
\frac{1}{1.14 \times 10^{-3}+3.15 \times 10^{-2}+1.8 \times 10^{-4}+2.86 \times 10^{-4}}=30 \mathrm{~s}
\end{gathered}
$$

The principal sink for ClO is reaction 5 , with NO .
2. The Cl atoms produced from reaction (3) react mainly with $\mathrm{O}_{3}$ to propagate the catalytic cycle. In contrast, most of the ClO molecules produced from reaction (1) react with NO instead of with O . The ratelimiting step in the catalytic cycle for $\mathrm{O}_{3}$ loss is thus reaction (3).
3. If ClO reacts with NO , we have the reaction sequence:

$$
\begin{gathered}
\mathrm{Cl}+\mathrm{O}_{3} \rightarrow \mathrm{ClO}+\mathrm{O}_{2} \\
\mathrm{ClO}+\mathrm{NO} \rightarrow \mathrm{Cl}+\mathrm{NO}_{2} \\
\mathrm{NO}_{2}+\mathrm{hv} \rightarrow \mathrm{NO}+\mathrm{O} \\
\mathrm{O}+\mathrm{O}_{2}+\mathrm{M} \rightarrow \mathrm{O}_{3}+\mathrm{M}
\end{gathered}
$$

(NULL CYCLE)
This is not a catalytic cycle for $\mathrm{O}_{3}$ loss.
4. Catalytic cycle for $\mathrm{O}_{3}$ loss involving formation of HOCl :

$$
\begin{aligned}
\mathrm{Cl}+\mathrm{O}_{3} & \rightarrow \mathrm{ClO}+\mathrm{O}_{2} \\
\mathrm{ClO}+\mathrm{HO}_{2} & \rightarrow \mathrm{HOCl}+\mathrm{O}_{2} \\
\mathrm{HOCl}+\mathrm{hv} & \rightarrow \mathrm{OH}+\mathrm{Cl} \\
\mathrm{OH}+\mathrm{O}_{3} & \rightarrow \mathrm{HO}_{2}+\mathrm{O}_{2}
\end{aligned}
$$

Net: $2 \mathrm{O}_{3} \rightarrow 3 \mathrm{O}_{2}$
The rate-limiting step for this catalytic cycle is the reaction $\mathrm{ClO}+\mathrm{HO}_{2}(6)$, while the rate-limiting step for the catalytic cycle in question 2 is $\mathrm{ClO}+\mathrm{O}$ (3). Each cycle results in the loss of two $\mathrm{O}_{\mathrm{x}}$ molecules per cycle. The ratio $R$ between the rates of $\mathrm{O}_{\mathrm{x}}$ loss is

$$
R=\frac{2 k_{6}[\mathrm{ClO}]\left[\mathrm{HO}_{2}\right]}{2 k_{3}[\mathrm{ClO}][\mathrm{O}]}=\frac{k_{6}\left[\mathrm{HO}_{2}\right]}{k_{3}[\mathrm{O}]}=0.16
$$

The catalytic cycle in question 2 is six times faster.
5. Lifetime of $\mathrm{ClO}_{x}$ :

$$
\tau_{\mathrm{ClO}_{x}}=\frac{[\mathrm{ClO}]+[\mathrm{Cl}]}{k_{2}[\mathrm{Cl}]\left[\mathrm{CH}_{4}\right]+k_{6}[\mathrm{ClO}]\left[\mathrm{HO}_{2}\right]+k_{7}[\mathrm{ClO}]\left[\mathrm{NO}_{2}\right]}
$$

We can assume steady state for the Cl atoms,

$$
\frac{[C l]}{[C l O]}=\frac{\tau_{C l}}{\tau_{C l O}}=1.2 \times 10^{-3} \mathrm{~mol} / \mathrm{mol}
$$

Replacing in the above expression $r=[\mathrm{Cl}] /[\mathrm{ClO}]=1.2 \times 10^{-3} \mathrm{~mol} / \mathrm{mol}$, and noting that $r \ll 1$ :

$$
\begin{gathered}
\tau_{\mathrm{ClO} x}=\frac{1}{k_{2} r\left[\mathrm{CH}_{4}\right]+k_{6}\left[\mathrm{HO}_{2}\right]+k_{7}\left[\mathrm{NO}_{2}\right]}=\frac{1}{8.7 \times 10^{-6}+1.78 \times 10^{-4}+2.86 \times 10^{-4}} \\
=2.1 \times 10^{3} \mathrm{~s}=35 \mathrm{~min}
\end{gathered}
$$

This lifetime is 70 times the lifetime of ClO . We conclude that efficient cycling takes place between Cl and ClO .

## 10. 6 Partitioning of $\mathrm{Cl}_{\mathrm{y}}$ in the stratosphere

1. 

$\tau_{\mathrm{Cl}}=\frac{[\mathrm{Cl}]}{k_{1}[\mathrm{Cl}]\left[\mathrm{O}_{3}\right]+k_{5}\left[\mathrm{CH}_{4}\right][\mathrm{Cl}]}=\frac{1}{k_{1}\left[\mathrm{O}_{3}\right]+k_{5}\left[\mathrm{CH}_{4}\right]} \approx \frac{1}{k_{1}\left[\mathrm{O}_{3}\right]}=0.025 \mathrm{~s}$

$$
\begin{aligned}
& \tau_{\mathrm{ClO}}=\frac{[\mathrm{ClO}]}{k_{2}[\mathrm{ClO}][\mathrm{NO}]+k_{3}[\mathrm{ClO}]\left[\mathrm{NO}_{2}\right]} \approx \frac{1}{k_{2}[\mathrm{NO}]}=36 \mathrm{~s} \\
& \tau_{\mathrm{ClNO}_{3}}=\frac{1}{k_{4}}=4.0 \text { hours } \\
& \tau_{\mathrm{HCl}}=\frac{1}{k_{6}[\mathrm{OH}]}=12 \text { days }
\end{aligned}
$$

2. Chemical steady state for Cl atoms:

$$
k_{1}[\mathrm{Cl}]\left[\mathrm{O}_{3}\right] \approx k_{2}[\mathrm{ClO}][\mathrm{NO}] \Rightarrow \frac{[\mathrm{ClO}]}{[\mathrm{Cl}]} \approx \frac{k_{1}\left[\mathrm{O}_{3}\right]}{k_{2}[\mathrm{NO}]}=1.4 \times 10^{3} \mathrm{~mol} / \mathrm{mol}
$$

Chemical steady state for $\mathrm{ClNO}_{3}$ :

$$
k_{3}[\mathrm{ClO}]\left[\mathrm{NO}_{2}\right]=k_{4}\left[\mathrm{ClNO}_{3}\right] \Rightarrow \frac{\left[\mathrm{ClNO}_{3}\right]}{[\mathrm{ClO}]}=\frac{k_{3}\left[\mathrm{NO}_{2}\right]}{k_{4}}=28 \mathrm{~mol} / \mathrm{mol}
$$

Therefore $\mathrm{ClNO}_{3}$ is the main component of $\mathrm{Cl}_{\mathrm{z}}$. The lifetime of $\mathrm{Cl}_{\mathrm{z}}$ is determined by the loss rate from conversion to HCl . Using the $\mathrm{Cl}_{\mathrm{z}}$ partitioning ratios which we have just derived,

$$
\begin{gathered}
\tau_{\mathrm{Clz}}=\frac{\left[\mathrm{Cl}_{z}\right]}{k_{5}[\mathrm{Cl}]\left[\mathrm{CH}_{4}\right]} \approx \frac{1}{k_{5}\left[\mathrm{CH}_{4}\right]} \frac{\left[\mathrm{ClNO}_{3}\right]}{[\mathrm{Cl}]} \approx \frac{1}{k_{5}\left[\mathrm{CH}_{4}\right]} \frac{k_{3}\left[\mathrm{NO}_{2}\right]}{k_{4}} \frac{k_{1}\left[\mathrm{O}_{3}\right]}{k_{2}[\mathrm{NO}]} \\
=\frac{k_{1} k_{3}}{k_{2} k_{4} k_{5}} \frac{\left[\mathrm{NO}_{2}\right]}{[\mathrm{NO}]} \frac{\left[\mathrm{O}_{3}\right]}{\left[\mathrm{CH}_{4}\right]}=9.0 \text { days }
\end{gathered}
$$

3. Since the lifetimes of the individual $\mathrm{Cl}_{\mathrm{z}}$ species are short, equilibration within the $\mathrm{Cl}_{\mathrm{y}}$ family is determined by the exchange between the HCl and $\mathrm{Cl}_{\mathrm{z}}$ reservoirs. The characteristic time $\tau$ for reaching steady state in the exchange between the two reservoirs is

$$
\tau=\left[\frac{1}{\tau_{\mathrm{HCl}}}+\frac{1}{\tau_{\mathrm{Clz}}}\right]^{-1}=5.1 \text { days }
$$

4. Chemical steady state for HCl :

$$
k_{5}[\mathrm{Cl}]\left[\mathrm{CH}_{4}\right]=k_{6}[\mathrm{HCl}][\mathrm{OH}]
$$

Also, from question 2,

$$
\frac{\left[\mathrm{ClNO}_{3}\right]}{[\mathrm{Cl}]}=\frac{k_{1} k_{3}\left[\mathrm{NO}_{2}\right]}{k_{2} k_{4}}\left[\mathrm{NO}_{3}\right]
$$

We thus obtain a relationship between $\mathrm{ClNO}_{3}$ and HCl :

$$
\frac{\left[\mathrm{ClNO}_{3}\right]}{[\mathrm{HCl}]}=\frac{k_{1} k_{3} k_{6}[\mathrm{OH}]\left[\mathrm{NO}_{2}\right]\left[\mathrm{O}_{3}\right]}{k_{2} k_{4} k_{5}\left[\mathrm{CH}_{4}\right][\mathrm{NO}]}
$$

Consider now steady state for $\mathrm{NO} / \mathrm{NO}_{2}$ :

$$
k_{7}[\mathrm{NO}]\left[\mathrm{O}_{3}\right]=k_{8}\left[\mathrm{NO}_{2}\right]
$$

and replace into the relationship between $\mathrm{ClNO}_{3}$ and HCl :

$$
\frac{\left[\mathrm{ClNO}_{3}\right]}{[\mathrm{HCl}]}=\frac{k_{1} k_{3} k_{6} k_{7}[\mathrm{OH}]\left[\mathrm{O}_{3}\right]^{2}}{k_{2} k_{4} k_{5} k_{8}\left[\mathrm{CH}_{4}\right]}
$$

The quadratic dependence of the ratio on $\left[\mathrm{O}_{3}\right]$ reflects the compounding of two factors through which $\mathrm{O}_{3}$ enhances $\mathrm{ClNO}_{3}$ concentrations relative to HCl : (1) as $\mathrm{O}_{3}$ increases, the Cl atom concentration decreases because of the $\mathrm{Cl}+\mathrm{O}_{3}$ reaction, so that formation of HCl is suppressed; (2) as $\mathrm{O}_{3}$ increases, the $\mathrm{NO}_{2}$ concentration increases because of the $\mathrm{NO}+\mathrm{O}_{3}$ reaction, and the resulting siphoning of ClO towards $\mathrm{ClNO}_{3}$ further reduces the Cl atom concentration.
5. The reaction $\mathrm{ClO}+\mathrm{OH} \rightarrow \mathrm{HCl}+\mathrm{O}_{2}$ provides an alternate pathway for converting $\mathrm{Cl}_{\mathrm{Z}}$ to HCl , thus decreasing the $\left[\mathrm{ClNO}_{3}\right] /[\mathrm{HCl}]$ ratio. By increasing the partitioning of $\mathrm{Cl}_{y}$ towards the inactive HCl reservoir, this reaction would slow down chlorine-catalyzed ozone loss.

## 10. 7 Bromine-catalyzed ozone loss

1. 

2.
(1)

$$
\begin{align*}
& \mathrm{Br}+\mathrm{O}_{3} \rightarrow \mathrm{BrO}+\mathrm{O}_{2}  \tag{1}\\
& \mathrm{BrO}+\mathrm{O} \rightarrow \mathrm{Br}+\mathrm{O}_{2} \tag{3}
\end{align*}
$$

(2)

$$
\begin{gather*}
\mathrm{Br}+\mathrm{O}_{3} \rightarrow \mathrm{BrO}+\mathrm{O}_{2}  \tag{1}\\
\mathrm{Cl}+\mathrm{O}_{3} \rightarrow \mathrm{ClO}+\mathrm{O}_{2}  \tag{11}\\
\mathrm{BrO}+\mathrm{ClO} \rightarrow \mathrm{Br}+\mathrm{Cl}+\mathrm{O}_{2}  \tag{5}\\
\left(\mathrm{Net}: 2 \mathrm{O}_{3} \rightarrow 3 \mathrm{O}_{2}\right)
\end{gather*}
$$

$$
\left(\text { Net: } \mathrm{O}_{3}+\mathrm{O} \rightarrow 2 \mathrm{O}_{2}\right)
$$

(3)

$$
\begin{gather*}
\mathrm{Br}+\mathrm{O}_{3} \rightarrow \mathrm{BrO}+\mathrm{O}_{2}  \tag{1}\\
\mathrm{OH}+\mathrm{O}_{3} \rightarrow \mathrm{HO}_{2}+\mathrm{O}_{2} \tag{15}
\end{gather*}
$$

$$
\begin{gather*}
\mathrm{BrO}+\mathrm{HO}_{2} \rightarrow \mathrm{HOBr}+\mathrm{O}_{2}  \tag{4}\\
\mathrm{HOBr}+h \nu \rightarrow \mathrm{OH}+\mathrm{Br} \tag{7}
\end{gather*}
$$

(Net: $2 \mathrm{O}_{3} \rightarrow 3 \mathrm{O}_{2}$ )

## 10. 8 Limitation of antarctic ozone depletion

1. Steady state for Cl atoms:

$$
\begin{gathered}
k_{2}[\mathrm{ClO}][\mathrm{NO}]=k_{1}[\mathrm{Cl}]\left[\mathrm{O}_{3}\right] \\
\frac{[\mathrm{Cl}]}{[\mathrm{ClO}]}=\frac{k_{2}[\mathrm{NO}]}{k_{1}\left[\mathrm{O}_{3}\right]}<\frac{k_{2}\left[\mathrm{NO}_{x}\right]}{k_{1}\left[\mathrm{O}_{3}\right]}=1.7 \times 10^{-3} \mathrm{~mol} / \mathrm{mol}
\end{gathered}
$$

Therefore $[\mathrm{Cl}] \ll[\mathrm{ClO}]$. Steady state for NO:

$$
\begin{gathered}
k_{4}\left[\mathrm{NO}_{2}\right]=k_{3}[\mathrm{NO}]\left[\mathrm{O}_{3}\right]+k_{2}[\mathrm{ClO}][\mathrm{NO}] \\
\frac{[\mathrm{NO}]}{\left[\mathrm{NO}_{2}\right]}=\frac{k_{4}}{k_{3}\left[\mathrm{O}_{3}\right]+k_{2}[\mathrm{ClO}]} \approx \frac{k_{4}}{k_{3}\left[\mathrm{O}_{3}\right]+k_{2}\left[\mathrm{ClO}_{x}\right]}=2.1 \times 10^{-2} \mathrm{~mol} / \mathrm{mol}
\end{gathered}
$$

Therefore $[\mathrm{NO}] \ll\left[\mathrm{NO}_{2}\right]$.
2. Lifetimes of Cl and NO :

$$
\begin{gathered}
\tau_{\mathrm{Cl}}=\frac{[\mathrm{Cl}]}{k_{1}[\mathrm{Cl}]\left[\mathrm{O}_{3}\right]}=0.06 \mathrm{~s} \\
\tau_{\mathrm{NO}}=\frac{[\mathrm{NO}]}{k_{2}[\mathrm{NO}][\mathrm{ClO}]+k_{3}[\mathrm{NO}]\left[\mathrm{O}_{3}\right]}=2 \mathrm{~s}
\end{gathered}
$$

Short lifetimes -> steady state assumption is OK.
3. Loss of $\mathrm{ClO}_{\mathrm{x}}$ is by reaction (5):

$$
\left.\tau_{C l O x}=\frac{\left[\mathrm{ClO}_{x}\right]}{k_{5}[\mathrm{Cl}][\mathrm{CH}}{ }_{4}\right]
$$

Steady state for Cl atoms:

$$
[\mathrm{Cl}]=\frac{k_{2}[\mathrm{ClO}][\mathrm{NO}]}{k_{1}\left[\mathrm{O}_{3}\right]} \approx \frac{k_{2}\left[\mathrm{ClO}_{\chi}\right][\mathrm{NO}]}{k_{1}\left[\mathrm{O}_{3}\right]}
$$

Steady state for NO:

$$
[\mathrm{NO}]=\frac{k_{4}\left[\mathrm{NO}_{2}\right]}{k_{3}\left[\mathrm{O}_{3}\right]+k_{2}[\mathrm{ClO}]} \approx \frac{k_{4}\left[\mathrm{NO}_{x}\right]}{k_{3}\left[\mathrm{O}_{3}\right]+k_{2}\left[\mathrm{ClO}_{x}\right]} \approx \frac{k_{4}\left[\mathrm{NO}_{x}\right]}{k_{2}\left[\mathrm{ClO}_{x}\right]}
$$

(since $k_{3}\left[\mathrm{O}_{3}\right] \ll k_{2}\left[\mathrm{ClO}_{\mathrm{x}}\right]$ )
Replacing,

$$
\tau_{C l O x}=\frac{k_{1}\left[\mathrm{O}_{3}\right]\left[\mathrm{ClO}_{x}\right]}{k_{4} k_{5}\left[\mathrm{NO}_{x}\right]\left[\mathrm{CH}_{4}\right]}
$$

Substituting numerical values, we find $\tau_{\mathrm{ClOx}}$ (days) $=3.8\left[\mathrm{O}_{3}\right](\mathrm{ppmv})$. As $\mathrm{O}_{3}$ concentrations decrease due to $\mathrm{ClO}_{x}$-catalyzed $\mathrm{O}_{3}$ loss, the $[\mathrm{Cl}] /[\mathrm{ClO}]$ ratio increases and reaction (5) becomes increasingly effective as a $\mathrm{ClO}_{\mathrm{x}}$ sink, limiting the extent of $\mathrm{O}_{3}$ depletion.

### 10.9 Fixing the ozone hole

1. Input the given initial concentrations into equations (1) - (7) sequentially, canceling products and reactants as they are used up:

$$
\begin{gather*}
1.5 \mathrm{ppbv} \mathrm{HCl}+0.3 \mathrm{ppbv} \mathrm{ClNO}_{3} \rightarrow 0.3 \mathrm{ppbv} \mathrm{Cl}_{2}+0.3 \mathrm{ppbv} \mathrm{HNO}_{3}+1.2 \mathrm{ppbv} \mathrm{HCl}  \tag{1}\\
1.2 \mathrm{ppbv} \mathrm{HCl}+1.8 \mathrm{ppbv} \mathrm{~N}_{2} \mathrm{O}_{5} \rightarrow 1.2 \mathrm{ppbv} \mathrm{ClNO}_{2}+1.2 \mathrm{ppbv} \mathrm{HNO}_{3}+0.6 \mathrm{ppbv}_{2} \mathrm{O}_{5}  \tag{1}\\
0.6 \mathrm{ppbv} \mathrm{~N}_{2} \mathrm{O}_{5}+\text { excess } \mathrm{H}_{2} \mathrm{O} \rightarrow 1.2 \mathrm{ppbv} \mathrm{HNO}_{3}  \tag{2}\\
0.3 \mathrm{ppbv} \mathrm{Cl}_{2}+\mathrm{hv} \rightarrow 0.6 \mathrm{ppbv} \mathrm{Cl}  \tag{3}\\
1.2 \mathrm{ppbv} \mathrm{ClNO}_{2}+\mathrm{hv} \rightarrow 1.2 \mathrm{ppbv} \mathrm{Cl}+1.2 \mathrm{ppbv} \mathrm{NO}_{2}  \tag{4}\\
1.8 \mathrm{ppbv} \mathrm{Cl}+\text { excess } \mathrm{O}_{3} \rightarrow 1.8 \mathrm{ppbv} \mathrm{ClO}+1.8 \mathrm{ppbv} \mathrm{O}_{2}  \tag{7}\\
1.2 \mathrm{ppbv} \mathrm{ClO}+1.2 \mathrm{ppbv} \mathrm{NO}_{2}+\mathrm{M} \rightarrow 1.2 \mathrm{ppbv} \mathrm{ClNO}_{3}+\mathrm{M} \tag{5}
\end{gather*}
$$

Thus we end up with $1.2 \mathrm{ppbv} \mathrm{ClNO}_{3}$ and $0.6 \mathrm{ppbv}(\mathrm{Cl}+\mathrm{ClO})$.
2. Add 1.8 ppbv $\mathrm{C}_{2} \mathrm{H}_{6}$ after the above reactions have occurred. First, $\mathrm{C}_{2} \mathrm{H}_{6}$ reacts with the 0.6 ppbv of $\mathrm{Cl} /$ ClO:

$$
\begin{gather*}
0.6 \mathrm{ppbv} \mathrm{Cl}+1.8 \mathrm{ppbv} \mathrm{C}_{2} \mathrm{H}_{6} \rightarrow 0.6 \mathrm{ppbv} \mathrm{HCl}+0.6 \mathrm{ppbv} \mathrm{C}_{2} \mathrm{H}_{5}+1.2 \mathrm{ppbv} \mathrm{C}_{2} \mathrm{H}_{6}  \tag{8}\\
0.6 \mathrm{ppbv} \mathrm{HCl}+1.2 \mathrm{ppbv} \mathrm{ClNO}_{3} \rightarrow 0.6 \mathrm{ppbv} \mathrm{Cl}_{2}+0.6 \mathrm{ppbv} \mathrm{ClNO}_{3}+0.6 \mathrm{ppbv} \mathrm{HNO}_{3}  \tag{1}\\
0.6 \mathrm{ppbv} \mathrm{Cl}_{2}+\mathrm{hv} \rightarrow 1.2 \mathrm{ppbv} \mathrm{Cl}  \tag{3}\\
1.2 \mathrm{ppbv} \mathrm{Cl}+1.2 \mathrm{ppbv} \mathrm{C}_{2} \mathrm{H}_{6} \rightarrow 1.2 \mathrm{ppbv} \mathrm{HCl}+1.2 \mathrm{ppbv} \mathrm{C}_{2} \mathrm{H}_{5} \tag{8}
\end{gather*}
$$

$$
\begin{gather*}
1.2 \mathrm{ppbv} \mathrm{HCl}+0.6 \mathrm{ppbv} \mathrm{ClNO}_{3} \rightarrow 0.6 \mathrm{ppbv} \mathrm{Cl}_{2}+0.6 \mathrm{ppbv} \mathrm{HNO}_{3}+0.6 \mathrm{ppbv} \mathrm{HCl}  \tag{1}\\
0.6 \mathrm{ppbv} \mathrm{Cl}_{2}+\mathrm{hv} \rightarrow 1.2 \mathrm{ppbv} \mathrm{Cl} \tag{3}
\end{gather*}
$$

Thus we end up with $1.2 \mathrm{ppbv}(\mathrm{Cl}+\mathrm{ClO}), 0.6 \mathrm{ppbv} \mathrm{HCl}$, and zero $\mathrm{ClNO}_{3}$.
This amount of ethane injection would actually increase the amount of Cl and ClO present, thus increasing the potential for ozone loss.
3. Since we have no more $\mathrm{ClNO}_{3}$ left to turn HCl into Cl , we can convert all $\mathrm{Cl} / \mathrm{ClO}$ to HCl by adding 1.2 ppbv more $\mathrm{C}_{2} \mathrm{H}_{6}$ (total of 3 ppbv ).

## 10. 10 PSC formation

1. Phase rule: $n=c+2-p$. Here $c=2$, so $p=4$ implies $n=0$. Coexistence of four phases is possible but only for specific points (not regions) in the ( $T, P_{H 2 O}, P_{H N O 3}$ ) space. B, D, Q are such points.
2. NAT and $\mathrm{H}_{2} \mathrm{O}$ ice particles coexist at equilibrium along the line starting from point B . The temperature must be less than about 235 K (temperature of point B ).
3.1 The PSC particles will form at about 195 K , with a composition of $\mathrm{HNO}-3 \mathrm{H}_{2} \mathrm{O}$ (NAT).
$3.2 \mathrm{H}_{2} \mathrm{O}$ and $\mathrm{HNO}_{3}$ are gradually depleted from the gas phase according to the NAT stoichiometry, meaning that $\mathrm{H}_{2} \mathrm{O}$ is being depleted three times as quickly as $\mathrm{HNO}_{3}$. However, there is 100 times as much $\mathrm{H}_{2} \mathrm{O}$ available, thus eventually $\mathrm{HNO}_{3}$ will be titrated and $\mathrm{H}_{2} \mathrm{O}$ ice will form.

## SOLUTIONS TO PROBLEMS, CHAPTER 11

## 11. 1 Sources of CO

1. If $\mathrm{CH}_{4}$ oxidation were the only source of CO , then the concentration of CO would be determined by the chemical steady state,

$$
k_{1}\left[\mathrm{CH}_{4}\right][\mathrm{OH}]=k_{2}[\mathrm{CO}][\mathrm{OH}] \Rightarrow[\mathrm{CO}]=\frac{k_{1}}{k_{2}}\left[\mathrm{CH}_{4}\right]=\frac{2.5 \times 10^{-15}}{1.5 \times 10^{-13}} \cdot 1700=28 \mathrm{ppbv}
$$

Therefore, $\mathrm{CH}_{4}$ oxidation contributes $28 / 80=35 \%$ of the CO source in the northern hemisphere and 28/ $50=56 \%$ of the CO source in the southern hemisphere, reflecting the concentration of combustion sources in the northern hemisphere. Note that the CO lifetime is sufficiently short (2 months) that interhemispheric transport can be neglected in the CO budget for each hemisphere.

## 11. 2 Estimating the global source of tropospheric ozone

## 1.

The net source $F_{S T}$ of tropospheric ozone contributed by transport from the stratosphere is given by

$$
F_{S T}=k_{S T} N_{O 3 S}-k_{T S} N_{O 3 T}=\left(k_{S T} f_{S}+k_{T S}\left(1-f_{S}\right)\right) N_{O 3}
$$

where $N_{O 3}=5 \times 10^{13}$ moles is the total amount of $\mathrm{O}_{3}$ in the atmosphere and $f_{S}=0.9$ is the stratospheric fraction. Substituting numerical values we find $F_{S T}=3 \times 10^{13}$ moles $\mathrm{yr}^{-1}$.
2.1 Net reaction for oxidation of CO to $\mathrm{CO}_{2}$ :

$$
\mathrm{CO}+2 \mathrm{O}_{2} \rightarrow \mathrm{CO}_{2}+\mathrm{O}_{3}
$$

Net reaction for oxidation of $\mathrm{CH}_{4}$ to $\mathrm{CO}_{2}$ :

$$
\mathrm{CH}_{4}+8 \mathrm{O}_{2} \rightarrow 4 \mathrm{O}_{3}+\mathrm{CO}_{2}+2 \mathrm{H}_{2} \mathrm{O}
$$

So, the yields are 4 molecules of ozone per molecule of methane oxidized and 1 molecule of ozone per molecule of carbon monoxide oxidized.
2.2

$$
4\left(3 \times 10^{13}\right)+1\left(4 \times 10^{13}\right)=1.6 \times 10^{14}{\text { moles } \mathrm{yr}^{-1}}^{-1}
$$

2.3 Our simple model assumed high $-\mathrm{NO}_{x}$ conditions and hence an upper limit for the $\mathrm{O}_{3}$ yield from oxidation of CO and $\mathrm{CH}_{4}$. In the more complicated models of the actual atmosphere, reactions of peroxy radicals with species other than NO (such as for example the $\mathrm{HO}_{2}+\mathrm{HO}_{2}$ reaction) will reduce the $\mathrm{O}_{3}$ yield.
2.4 Chemical production within the troposphere is the dominant source of tropospheric ozone.

### 11.3 Oxidizing power of the atmosphere

1.1 Calculate how many $\mathrm{CH}_{3} \mathrm{O}_{2}$ molecules are produced by oxidizing one methane molecule to $\mathrm{CO}_{2}$.
a. 1 molecule $\mathrm{CH}_{3} \mathrm{O}_{2}$ is produced in (1)
b. $2 / 3$ of this $\mathrm{CH}_{3} \mathrm{O}_{2}$ reacts by (2a), producing $2 / 3$ molecule $\mathrm{CH}_{3} \mathrm{OOH}$
c. this $2 / 3$ molecule $\mathrm{CH}_{3} \mathrm{OOH}$ reacts by (3); $1 / 3$ of it, or $(2 / 3)(1 / 3)=2 / 9$, reacts by ( 3 c ), producing $2 / 9$ molecule $\mathrm{CH}_{3} \mathrm{O}_{2}$
d. $2 / 3$ of this $\mathrm{CH}_{3} \mathrm{O}_{2}$ reacts by (2a), i.e., step b., and the cycle continues indefinitely, each time producing $(2 / 9)^{\mathrm{n}} \mathrm{CH}_{3} \mathrm{O}_{2}$, where $\mathrm{n}=\{0,1,2, \ldots\}$

We thus have an infinite series $1+x+x^{2}+x^{3}+\ldots=1 /(1-x)$ with $x=2 / 9$. The total $\mathrm{CH}_{3} \mathrm{O}_{2}$ produced is $9 /$ $7=1.29$
1.2 OH is consumed in reactions $1,3 \mathrm{c}, 4 \mathrm{c}$, and 5 ; it is produced in reaction 3 a ( 3 b has no net effect).

Net OH consumed $=(1)+(5)+(2 \mathrm{a})(3 \mathrm{c})+(4 \mathrm{c})-(2 \mathrm{a})(3 \mathrm{a})=1+1+(9 / 7)(2 / 3)(1 / 3)+1 / 4-(9 / 7)(2 / 3)(1 / 3)=$ 2.25 molecules consumed.
1.3 Net $\mathrm{HO}_{2}$ produced? $\mathrm{HO}_{2}$ consumed in reaction 2a but produced in reactions $2 \mathrm{~b}, 3 \mathrm{a}, 4 \mathrm{a}(2 \mathrm{x}), 4 \mathrm{c}$, and 5 . Net produced $=-(2 \mathrm{a})+(2 \mathrm{~b})+(2 \mathrm{a})(3 \mathrm{a})+2(4 \mathrm{a})+(4 \mathrm{c})+(5)=-(9 / 7)(2 / 3)+(9 / 7)(1 / 3)+(9 / 7)(2 / 3)(1 / 3)+$ $2(1 / 2)+1 / 4+1=2.11$
1.4 2.25-2.11 = 0.14 molecules of $\mathrm{HO}_{\mathrm{x}}$ are consumed in oxidizing one molecule $\mathrm{CH}_{4}$ to $\mathrm{CO}_{2}$. If more $\mathrm{NO}_{\mathrm{x}}$ were present to favor (2b) over (2a), the oxidation of $\mathrm{CH}_{4}$ would become a net $\mathrm{HO}_{x}$ source.
2.1 The net effect of $\mathrm{H}_{2} \mathrm{O}_{2}$ formation on the recycling of $\mathrm{HO}_{2}$ to OH can be determined by adding (6c) and the two reaction branches for $\mathrm{H}_{2} \mathrm{O}_{2}$ :

$$
\begin{aligned}
\mathrm{HO}_{2}+\mathrm{HO}_{2} & \rightarrow 2 \mathrm{OH}+\mathrm{O}_{2} \\
\mathrm{HO}_{2}+\mathrm{OH} & \rightarrow \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2}
\end{aligned}
$$

What fraction of $\mathrm{HO}_{2}$ is recycled to OH ? $=(6 \mathrm{a})+(6 \mathrm{~b})+(6 \mathrm{c})(7 \mathrm{a})-(6 \mathrm{c})(7 \mathrm{~b})=1 / 4+1 / 4+(1 / 2)(1 / 2)-(1 /$ 2) $(1 / 2)=0.5$ or $50 \%$
2.2 From methane to $\mathrm{CO}_{2}, 50 \%$ of the $2.11 \mathrm{HO}_{2}$ is actually recycled to OH , so that only 1.06 OH are actually consumed. From CO to $\mathrm{CO}_{2}, 0.5 \mathrm{OH}$ consumed.
2.3 Current OH source from photolysis $=2.9 \times 10^{11}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$. Current OH consumption from oxidation of $\mathrm{CH}_{4}$ and $\mathrm{CO}=1.06\left(1.2 \times 10^{11}\right)+0.5\left(1.9 \times 10^{11}\right)=2.2 \times 10^{11}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$. There is enough OH supplied to oxidize $\mathrm{CH}_{4}$ and CO .

What if methane emissions doubled? the additional OH consumption rate of $1.06\left(1.2 \times 10^{11}\right)$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ would bring the total OH consumption rate to $3.5 \times 10^{11}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$; OH would be titrated.

If CO emissions doubled, the additional OH consumption rate of $0.5\left(1.9 \times 10^{11}\right)$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ would
bring the total OH consumption rate to $3.2 \times 10^{11}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$; OH would be titrated.
2.4 If OH and $\mathrm{HO}_{2}$ were to decrease, the branching ratios would change. 2 b would increase relative to 2 a ; 3 a would increase relative to 3 c ; 4 a would increase relative to 4 c ; and 7 a would increase relative to 7 b . All three of these effects would act as negative feedbacks to prevent total titration of OH. For the branching ratios given in this problem, the effect on the branching ratio of (2) would be most important in view of the present dominance of 2 a .

## 11. 4 OH concentrations in the past

1. Oxidation of $\mathrm{CH}_{4}$ produces $\mathrm{CH}_{2} \mathrm{O}$ with a yield of unity (though the route through which $\mathrm{CH}_{2} \mathrm{O}$ is produced might vary, depending in particular on the abundance of $\mathrm{NO}_{\mathrm{x}}$ ). The lifetime of $\mathrm{CH}_{2} \mathrm{O}$ is sufficiently short (1 day) that chemical steady state can be assumed:

$$
\begin{gathered}
\frac{d\left[\mathrm{CH}_{2} \mathrm{O}\right]}{d t}=\mathrm{k}^{\prime}\left[\mathrm{CH}_{4}\right][\mathrm{OH}]-\mathrm{k}\left[\mathrm{CH}_{2} \mathrm{O}\right]=0 \\
\mathrm{CH}_{2} \mathrm{O}=\frac{k^{\prime}}{k}\left[\mathrm{CH}_{4}\right][\mathrm{OH}]
\end{gathered}
$$

2.1 Rearrange this equation to solve for $[\mathrm{OH}]$ :

$$
[\mathrm{OH}]=\frac{\left[\mathrm{CH}_{2} \mathrm{O}\right] k}{\left[\mathrm{CH}_{4}\right] \mathrm{k}^{\prime}}
$$

Present $[\mathrm{OH}]=1.9 \times 10^{5}$ molecules $\mathrm{cm}^{-3}$
Pre-industrial $[\mathrm{OH}]=2.3 \times 10^{5}$ molecules $\mathrm{cm}^{-3}$
Glacial $[\mathrm{OH}]=1.1 \times 10^{5}$ molecules $\mathrm{cm}^{-3}$
2.2 The OH decrease from preindustrial to today suggested by the ice core data could be explained by increases in $\mathrm{CH}_{4}$ and CO .
2.3 Atmospheric concentrations of $\mathrm{N}_{2} \mathrm{O}, \mathrm{CH}_{4}$, and $\mathrm{H}_{2} \mathrm{O}$ were all lower in glacial times; $\mathrm{N}_{2} \mathrm{O}$ and $\mathrm{CH}_{4}$ because of the less active biosphere, $\mathrm{H}_{2} \mathrm{O}$ because of the lower atmospheric temperatures. As a result, catalytic $\mathrm{O}_{3}$ loss in the stratosphere would be less. In addition, less convective activity in the glacial period would result in a lower tropopause and a thicker stratosphere. A thicker stratospheric $\mathrm{O}_{2}$ layer would decrease the UV flux reaching the the troposphere and therefore the production of OH in the troposphere.

## 11. 5 Acetone in the upper troposphere

1. How many molecules of $\mathrm{O}_{3}$ and HOx are produced in the complete oxidation of acetone to $\mathrm{CO}_{2}$ ?

The numbers refer to the reactions. Notice that 2 molecules of $\mathrm{CH}_{3} \mathrm{O}_{2}$ are formed, so reactions (4), (5) and (6) all proceed twice. Two $\mathrm{CO}_{2}$ are formed from reactions (4) through (6) and one is formed from reaction (2). Two HOx are formed when reaction (4) proceeds twice and 4 HOx are formed when reaction (5) proceeds twice. Notice that reaction (6) contributes no net HOx production or loss, but does convert OH to $\mathrm{HO}_{2}$ which participates in ozone production. The number of $\mathrm{NO}_{2}$ formed corresponds to the number of $\mathrm{O}_{3}$ formed - $1 \mathrm{NO}_{2}$ is formed in reaction (2), $2 \mathrm{NO}_{2}$ are formed from reaction (4) taking place twice, 8 $\mathrm{NO}_{2}$ are formed from reaction (7) with $\mathrm{HO}_{2}$. The net reaction for this mechanism is:

$$
\mathrm{CH}_{3} \mathrm{COCH}_{3}+22 \mathrm{O}_{2}+\mathrm{hv}-\cdots------>3 \mathrm{CO}_{2}+11 \mathrm{O}_{3}+6 \mathrm{OH}
$$

2. Compare sources of HOx from photolysis of acetone and from photolysis of $\mathrm{O}_{3}$.

The loss rate of acetone is $k_{1}$ [Acetone]. The corresponding $\mathrm{HO}_{\mathrm{x}}$ source is $S_{H O x}=n k_{1}$ [Acetone] where $n=$ 6 is the $\mathrm{HO}_{\mathrm{x}}$ yield from the oxidation of acetone to $\mathrm{CO}_{2}$. Substituting numerical values we find $S_{H O x}=$ $6 \times 3.7 \times 10^{-7} \times 5 \times 10^{-10} \times 8 \times 10^{18}=9 \times 10^{3}$ molecules $\mathrm{HO}_{\mathrm{x}}$ produced per acetone molecule consumed.

The $\mathrm{HO}_{x}$ source from photolysis of $\mathrm{O}_{3}$ is $S_{H O x}=2 k_{10}\left[\mathrm{O}\left({ }^{1} \mathrm{D}\right)\right]\left[\mathrm{H}_{2} \mathrm{O}\right]$. From the chemical steady state equation for $\mathrm{O}\left({ }^{1} \mathrm{D}\right)$,

$$
\left[\mathrm{O}\left({ }^{1} \mathrm{D}\right)\right]=\frac{\mathrm{k}_{8}\left[\mathrm{O}_{3}\right]}{\mathrm{k}_{9}[\mathrm{M}]+\mathrm{k}_{10}\left[\mathrm{H}_{2} \mathrm{O}\right]}
$$

and therefore

$$
S_{H O x}=\frac{2 \mathrm{k}_{10}\left[\mathrm{H}_{2} \mathrm{O}\right] \mathrm{k}_{8}\left[\mathrm{O}_{3}\right]}{\mathrm{k}_{9}[\mathrm{M}]+\mathrm{k}_{10}\left[\mathrm{H}_{2} \mathrm{O}\right]}=3.3 \times 10^{3} \text { molecules } \mathrm{cm}^{-3}
$$

Acetone therefore dominates as a source of $\mathrm{HO}_{x}$.
3. The reaction $\mathrm{O}(1 \mathrm{D})+\mathrm{H}_{2} \mathrm{O}$ is much faster in the lower troposphere (more $\left.\mathrm{H}_{2} \mathrm{O}\right)$ and in the stratosphere (more $\mathrm{O}_{3}$ ) and will thus dominate there as a source of $\mathrm{HO}_{\mathrm{x}}$ over the photolysis of acetone.
4.1. In the oxidation of one molecule of CO to $\mathrm{CO}_{2}, 1$ molecule of $\mathrm{O}_{3}$ is produced and no $\mathrm{HO}_{x}$ is produced.
4.2. First, look at the ozone production rate from oxidation of CO :

$$
P_{O 3}=\frac{[\mathrm{CO}]}{\tau_{\mathrm{CO}}}=\left(\frac{1}{3 \mathrm{mon}}\right)\left(\frac{1 \text { mon }}{30 \mathrm{day}}\right)\left(\frac{1 \text { day }}{86400 \mathrm{~s}}\right)\left(\frac{100 \mathrm{ppb} \cdot \mathrm{M}}{10^{9}}\right)=1.1 \times 10^{5 \mathrm{molec}} \frac{\mathrm{~cm}^{3} \mathrm{~s}}{}
$$

Next, look at the ozone production rate from oxidation of acetone:

$$
P_{\mathrm{O} 3}=11 k_{1}\left[\mathrm{CH}_{3} \mathrm{COCH}_{3}\right]=1.6 \times 10 \frac{4 \mathrm{molec}}{\mathrm{~cm}^{3} \mathrm{~s}}
$$

The direct source of $\mathrm{O}_{3}$ from oxidation of acetone is minor compared to that from oxidation of CO . However, the oxidation of acetone is a major source of $\mathrm{HO}_{x}$. Increasing acetone in the upper troposphere would increase $\mathrm{HO}_{\mathrm{x}} \rightarrow$ decrease $\tau_{\mathrm{CO}} \rightarrow$ increase $\mathrm{O}_{3}$ production. Ozone production in the upper troposphere is thus sensitive to acetone because of its effect on the CO oxidation rate.

## 11. 6 Transport, rainout, and chemistry in the marine upper troposphere

1. The residence time of air in the upper troposphere is $\tau_{3}=1 / k_{32}$. The masses of air $m_{i}$ in each layer are proportional to their pressure thicknesses $\Delta P_{i}=P_{i}($ bottom $)-P_{i}$ (top). We therefore use $\Delta P_{i}$ as measure of the mass (or number of moles) of air in a layer. We obtain a relationship between $k_{13}$ and $k_{32}$ by considering the mass balance of air in the upper troposphere:

$$
k_{13} \Delta P_{1}=k_{32} \Delta P_{3} \Rightarrow k_{13}=\frac{\Delta P_{3}}{\Delta P_{1}} k_{32}
$$

We now apply the steady-state equation for $\mathrm{CH}_{3} \mathrm{I}$ in the upper troposphere:

$$
k_{13}\left[\mathrm{CH}_{3} I\right]_{1} \Delta P_{1}=\left(k+k_{32}\right)\left[\mathrm{CH}_{3} I\right]_{3} \Delta P_{3}
$$

where the bracketed concentrations are mixing ratios as given in the problem, and $k=0.25$ day $^{-1}$ is the $\mathrm{CH}_{3} \mathrm{I}$ photolysis rate constant. Substituting $k_{13}$ from the first equation, we cancel the $\Delta P$ terms:

$$
k_{32}\left[\mathrm{CH}_{3} I\right]_{1}=\left(k+k_{32}\right)\left[\mathrm{CH}_{3} \mathrm{I}\right]_{3}
$$

and obtain an expression for $k_{32}$ :

$$
k_{32}=\frac{k\left[\mathrm{CH}_{3} I\right]_{3}}{\left[\mathrm{CH}_{3} \mathrm{I}\right]_{1}-\left[\mathrm{CH}_{3} \mathrm{I}\right]_{3}}=\frac{0.25 \cdot 0.10}{0.36-0.10}=9.6 \times 10^{-2} \mathrm{~s}^{-1}
$$

The residence time of air in the upper troposphere is therefore $\tau_{3}=1 / 0.096=10$ days.
2. By definition of the Henry's Law constant,

$$
K_{X}=\frac{\{X\}_{a q}}{P_{X}}
$$

where $P_{X}$ is the partial pressure of $X$ in the gas phase, and $\{X\}_{\text {aq }}$ is the cloudwater concentration in moles per unit volume of water. We use the cloud liquid water content to relate $\{X\}_{\mathrm{aq}}$ to $[X]_{\mathrm{aq}}$ :

$$
[X]_{a q}=L\{X\}_{a q}
$$

and we use the Ideal Gas Law to relate $P_{X}$ to $[\mathrm{X}]_{g}$ :

$$
P_{X}=[X]_{g} R T
$$

We thus obtain the relationship:

$$
f=\frac{[X]_{a q}}{[X]_{g}}=K_{X} L R T
$$

3. The Henry's Law constants are given in customary units of $M$ atm $^{-1}$. To avoid confusion, let us convert to SI units: $1 \mathrm{M} \mathrm{atm}{ }^{-1}=1 \mathrm{~mole}^{-1} \mathrm{~atm}^{-1}=10^{-2}$ mole $\mathrm{m}^{-3} \mathrm{~Pa}^{-1}$. Substituting numerical values of $K_{X}$ for $\mathrm{H}_{2} \mathrm{O}_{2}$ and $\mathrm{CH}_{3} \mathrm{OOH}$, we obtain $f_{\mathrm{H} 2 \mathrm{O} 2}=2 \times 10^{3} \times 1 \times 10^{-6} \times 8.31 \times 250=4.2$ and $f_{\mathrm{CH} 3 \mathrm{OOH}}=0.06$. We find that $\mathrm{H}_{2} \mathrm{O}_{2}$ in a cloud fractionates preferentially in the cloudwater and is therefore efficiently scavenged by rainout, in contrast, $\mathrm{CH}_{3} \mathrm{OOH}$ is not efficiently scavenged.
4. The net source $S_{\text {СНЗ }}$ OOH (molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}$ ) of $\mathrm{CH}_{3} \mathrm{OOH}$ to the upper troposphere by deep convection is

$$
\begin{aligned}
& S_{\mathrm{CH} 3 \mathrm{OOH}}=n_{a} k_{32}\left(\left[\mathrm{CH}_{3} \mathrm{OOH}\right]_{1}-\left[\mathrm{CH}_{3} \mathrm{OOH}\right]_{3}\right)=4 \times 10^{18} \cdot \frac{0.1}{86400} \cdot(1100-80) \cdot 10^{-12} \\
&=5 \times 10^{3} \text { molecules } \mathrm{cm}^{-3} \mathrm{~s}^{-1}
\end{aligned}
$$

5. Yield of $\mathrm{HO}_{x}=2 x(1 a)+2 x(2 b)=2(1 / 2)+2(1 / 3)=1.7$

The resulting source of $\mathrm{HO}_{x}$ is
$S_{H O x}=\left(\mathrm{HO}_{\mathrm{x}}\right.$ yield $) S_{\mathrm{CH} 3 O O H}=1.7 \times 5 \times 10^{3}=8.5 \times 10^{3}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}$.

This source is comparable to the $\mathrm{HO}_{x}$ source of $1 \mathrm{x} 10^{4}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}$ from the $\mathrm{O}\left({ }^{1} \mathrm{D}\right)+\mathrm{H}_{2} \mathrm{O}$ reaction. Convective injection of $\mathrm{CH}_{3} \mathrm{OOH}$ is therefore an important source of $\mathrm{HO}_{x}$ in the upper troposphere.

## 11. 7 Catalytic ozone destruction in the troposphere

1. 

Catalytic $\mathrm{O}_{3}$ loss mechanism:
$2\left(\mathrm{Br}+\mathrm{O}_{3} \rightarrow \mathrm{BrO}+\mathrm{O}_{2}\right)$
$\mathrm{BrO}+\mathrm{BrO} \rightarrow 2 \mathrm{Br}+\mathrm{O}_{2}$

Net: $2 \mathrm{O}_{3} \rightarrow 3 \mathrm{O}_{2}$
2. Reactions 2, 3, and 5 are sinks for BrO :

$$
\begin{gathered}
\frac{\text { rate } 2}{\text { rate } 3}=\frac{k_{2}}{2 k_{3}[B r O]}>\frac{k_{2}}{2 k_{3}\left[B r_{y}\right]}=\frac{1 \times 10^{-2}}{2 \cdot 3 \times 10^{-12} \cdot 50 \times 10^{-12} \cdot 3 \times 10^{19}}=1.1 \\
\frac{\text { rate } 2}{\text { rate } 5}=\frac{k_{2}}{k_{5}\left[H O_{2}\right]}=67
\end{gathered}
$$

So reaction (2) is the principal BrO sink. Now, consider the Br sinks:

$$
\frac{\text { rate } 1}{\text { rate } 4}=\frac{k_{1}\left[\mathrm{O}_{3}\right]}{k_{4}\left[\mathrm{CH}_{2} \mathrm{O}\right]}=4
$$

Most of the cycling between Br and BrO therefore takes place by (1)+(2), which is a null cycle. Since the rate of catalytic $\mathrm{O}_{3}$ loss by $(1)+(3)$ is determined by the competition between (2) and (3) for BrO , reaction (3) is the limiting step for catalytic $\mathrm{O}_{3}$ loss.
3. Since reaction (3) is the rate-limiting step for $\mathrm{O}_{3}$ loss:

$$
\frac{-d\left[\mathrm{O}_{3}\right]}{d t}=2 k_{3}[\mathrm{BrO}]^{2}
$$

Assuming that $[\mathrm{BrO}] \approx\left[\mathrm{Br}_{\mathrm{y}}\right]=50$ pptv, we find
$-d\left[\mathrm{O}_{3}\right] / d t=2 \times 3 \times 10^{-12} \times\left(50 \times 10^{-12} \times 3 \times 10^{19}\right)^{2}=1.4 \times 10^{7}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}=39 \mathrm{ppbv}$ day ${ }^{-1}$. There would be near-total $\mathrm{O}_{3}$ depletion on a time scale of a day.
4.1 HBr and HOBr are non-radical reservoirs for $\mathrm{Br}_{\mathrm{y}}$; formation of HBr and HOBr will decrease the fraction of $\mathrm{Br}_{\mathrm{y}}$ present as BrO and therefore decrease the $\mathrm{O}_{3}$ loss rate.
4.2 We saw in question 2 that Br and BrO are mostly cycled between each other by reactions (1) and (2). The steady-state equation for Br atoms is therefore approximately

$$
k_{1}[\mathrm{Br}]\left[\mathrm{O}_{3}\right] \approx k_{2}[\mathrm{BrO}] \Rightarrow \frac{[\mathrm{Br}]}{[\mathrm{BrO}]} \approx \frac{k_{2}}{k_{1}\left[\mathrm{O}_{3}\right]}=0.014 \mathrm{~mol} / \mathrm{mol}
$$

This is one relationship between $\mathrm{Br}_{\mathrm{y}}$ species. We can get a second one from the steady-state equation for HOBr :

$$
k_{5}[\mathrm{BrO}]\left[\mathrm{HO}_{2}\right]=k_{7}[\mathrm{HOBr}] \Rightarrow \frac{[\mathrm{HOBr}]}{[\mathrm{BrO}]}=\frac{k_{5}\left[\mathrm{HO}_{2}\right]}{k_{7}}=1.5 \mathrm{~mol} / \mathrm{mol}
$$

and a third one from the steady-state equation for HBr :

$$
\begin{aligned}
k_{4}[\mathrm{Br}]\left[\mathrm{CH}_{2} \mathrm{O}\right]= & k_{6}[\mathrm{HBr}][\mathrm{OH}] \Rightarrow \frac{[\mathrm{HBr}]}{[\mathrm{Br}]}=\frac{k_{4}\left[\mathrm{CH}_{2} \mathrm{O}\right]}{k_{6}[\mathrm{OH}]}=160 \mathrm{~mol} / \mathrm{mol} \\
& \Rightarrow \frac{[H B r]}{[\mathrm{BrO}]}=160 \cdot 0.014=2.2 \mathrm{~mol} / \mathrm{mol}
\end{aligned}
$$

Finally we have the mass conservation equation for $\left[\mathrm{Br}_{\mathrm{y}}\right]$ :

$$
\begin{gathered}
{\left[\mathrm{Br}_{y}\right]=[\mathrm{Br}]+[\mathrm{BrO}]+[\mathrm{HOBr}]+[\mathrm{HBr}]} \\
\Rightarrow \\
\frac{\left[B r_{y}\right]}{[\mathrm{BrO}]}=\frac{[\mathrm{Br}]}{[\mathrm{BrO}]}+1+\frac{[\mathrm{HOBr}]}{[\mathrm{BrO}]}+\frac{[\mathrm{HBr}]}{[\mathrm{BrO}]}=4.7 \mathrm{~mol} / \mathrm{mol}
\end{gathered}
$$

The $50 \mathrm{pptv} \mathrm{Br}_{\mathrm{y}}$ are therefore partitioned into $11 \mathrm{pptv} \mathrm{BrO}, 16 \mathrm{pptv} \mathrm{HOBr}, 23 \mathrm{pptv} \mathrm{HBr}$, and 0.15 pptv Br . The $\mathrm{O}_{3}$ loss rate is $4.7^{2}=22$ times slower than calculated in question 3 . Ozone loss is now only 1.8 ppbv day $^{-1}$ and there would be little $\mathrm{O}_{3}$ depletion on a time scale of a few days.
4.3 The aerosol reaction $\mathrm{HBr}+\mathrm{HOBr}$, followed by $\mathrm{Br}_{2}$ photolysis, converts $\mathrm{Br}_{\mathrm{y}}$ from its non-radical inactive reservoirs into the $\mathrm{Br} / \mathrm{BrO}$ radicals active in catalyzing $\mathrm{O}_{3}$ loss. This mechanism is analogous to the aerosol reaction $\mathrm{HCl}+\mathrm{ClNO}_{3}$ taking place in the polar stratosphere.

## 11. 8 Nighttime oxidation of $\mathrm{NO}_{x}$

1. The mechanism operates only at night because $\mathrm{NO}_{3}$ would photolyze back to $\mathrm{NO}_{\mathrm{x}}$ in the daytime.
2. Conversion of $\mathrm{NO}_{2}$ to NO takes place only by photolysis, which does not operate at night; however, conversion of NO to $\mathrm{NO}_{2}$ by reaction (1) still takes place at night. Therefore, $\mathrm{NO}_{\mathrm{x}}$ at night is present entirely as $\mathrm{NO}_{2}$.
3. Calculate the lifetime of $\mathrm{NO}_{3}{ }^{*}$ at night:

$$
\tau_{\mathrm{NO}_{3}{ }^{*}}=\frac{\left[\mathrm{NO}_{3}\right]+\left[N_{2} O_{5}\right]}{k_{4}\left[N_{2} O_{5}\right]}=\frac{1}{k_{4}}\left(1+\frac{\left[\mathrm{NO}_{3}\right]}{\left[\mathrm{N}_{2} \mathrm{O}_{5}\right]}\right)
$$

Equilibrium (3) gives

$$
\begin{gathered}
\frac{\left[\mathrm{NO}_{3}\right]}{\left[\mathrm{N}_{2} \mathrm{O}_{5}\right]}=\frac{1}{K_{3}\left[\mathrm{NO}_{2}\right]} \\
\text { so } \tau_{\mathrm{NO}_{3}{ }^{*}}=\frac{1}{k_{4}}\left(1+\frac{1}{K_{3}\left[\mathrm{NO}_{2}\right]}\right)=2.0 \text { hours }
\end{gathered}
$$

Here we have used the data on pressure and temperature to calculate $n_{a}=2.3 \times 10^{19}$ molecules $\mathrm{cm}^{-3}$ and convert the mixing ratios to number densities.
4. Since $\mathrm{NO}_{3}{ }^{*}$ is in steady state, reaction (2) is the effective sink for $\mathrm{NO}_{x}$, and represents the loss of two $\mathrm{NO}_{\mathrm{x}}$ molecules (because $\mathrm{NO}_{3}$ combines with $\mathrm{NO}_{2}$ to consume an additional $\mathrm{NO}_{\mathrm{x}}$ molecule). Therefore the lifetime of $\mathrm{NO}_{\mathrm{x}}$ at night is

$$
\tau_{N O_{x}}=\frac{\left[N O_{x}\right]}{2 k_{2}\left[N O_{2}\right]\left[O_{3}\right]}=\frac{1}{2 k_{2}\left[O_{3}\right]}=7.5 \text { hours }
$$

The mechanism takes place only at night; therefore, for a 12-hour night, the lifetime of $\mathrm{NO}_{\mathrm{x}}$ averaged over 24 hours is $7.5 \mathrm{x}(24 / 12)=15$ hours. This lifetime is comparable to the 1 -day lifetime of $\mathrm{NO}_{\mathrm{x}}$ against oxidation by OH . Both sinks are of comparable importance.

### 11.9 Peroxyacetylnitrate (PAN) as a reservoir for $\mathrm{NO}_{x}$

1. Steady state for NO:

$$
\begin{gathered}
\mathrm{k}_{1}[\mathrm{NO}]\left[\mathrm{O}_{3}\right]=\mathrm{k}_{2}\left[\mathrm{NO}_{2}\right] \\
\frac{\left[\mathrm{NO}_{2}\right]}{[\mathrm{NO}]}=\frac{k_{1}\left[\mathrm{O}_{3}\right]}{k_{2}}
\end{gathered}
$$

Replace into $\left[\mathrm{NO}_{\mathrm{x}}\right]=[\mathrm{NO}]+\left[\mathrm{NO}_{2}\right]$ :

$$
\frac{\left[N O_{2}\right]}{\left[N O_{x}\right]}=\frac{1}{\left(1+\frac{k_{2}}{k_{1}\left[O_{3}\right]}\right)}
$$

The air density is $n_{a}=\aleph P / R T=6.023 \times 10^{23} \times 1 \times 10^{5} /(8.32 \times 298)=2.4 \times 10^{25}$ molecules $\mathrm{m}^{-3}=2.4 \times 10^{19}$ molecules $\mathrm{cm}^{-3}$. So $\left[\mathrm{O}_{3}\right]=100 \mathrm{ppbv}=2.4 \times 10^{12}$ molecules $\mathrm{cm}^{-3}$. Replacing numerical values for $k_{1}$ and $k_{2}$ (noon), we obtain $\left[\mathrm{NO}_{2}\right] /\left[\mathrm{NO}_{\mathrm{x}}\right]=0.81$. Further replacing $\left[\mathrm{NO}_{\mathrm{x}}\right]=100 \mathrm{ppbv}$ we obtain $\left[\mathrm{NO}_{2}\right]=81 \mathrm{ppbv}$ and $[\mathrm{NO}]=19 \mathrm{ppbv}$.

At other times of the day $k_{2}$ will be smaller, so $\left[\mathrm{NO}_{2}\right] /\left[\mathrm{NO}_{\mathrm{x}}\right]$ will increase. The presence of peroxy radicals will also increase the $\left[\mathrm{NO}_{2}\right] /\left[\mathrm{NO}_{\mathrm{x}}\right]$ ratio by providing an additional pathway for conversion of NO to $\mathrm{NO}_{2}$ :

$$
\mathrm{RO}_{2}+\mathrm{NO} \rightarrow \mathrm{RO}+\mathrm{NO}_{2}
$$

2. Steady state for PAN:

$$
k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]\left[\mathrm{NO}_{2}\right][\mathrm{M}]=k_{5}[\mathrm{PAN}]
$$

Steady state for the [PAN $\left.+\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]$ family:

$$
k_{3}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{CH}_{3}\right]=k_{4 a}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right][\mathrm{NO}]
$$

Replace, and use $\left[\mathrm{NO}_{2}\right] /[\mathrm{NO}]$ from question 1:

$$
[P A N]=\frac{k_{3} k_{4 b}}{k_{4 a} k_{5}}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{CH}_{3}\right] \frac{\left[\mathrm{NO}_{2}\right]}{[N O]}=\frac{k_{1} k_{3} k_{4 b}}{k_{2} k_{4 a} k_{5}}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{CH}_{3}\right]\left[\mathrm{O}_{3}\right]
$$

We see that the PAN concentration increases with increasing acetone and $\mathrm{O}_{3}$ but is insensitive to $\mathrm{NO}_{x}$.
To explain this result qualitatively, we note that $\mathrm{NO}_{\mathrm{x}}$ both suppresses PAN formation by reaction (4a) and promotes PAN formation by reaction (4b). Thus PAN formation depends not on the total $\mathrm{NO}_{\mathrm{x}}$ concentration, but on the $\left[\mathrm{NO}_{2}\right] /[\mathrm{NO}]$ ratio which determines the branching ratio (4b:4a). We saw in question 1 that the $\left[\mathrm{NO}_{2}\right] /[\mathrm{NO}]$ ratio is proportional to the $\mathrm{O}_{3}$ concentration, and hence PAN increases with increasing $\mathrm{O}_{3}$.
3. We introduce the schematic reaction (6),
$\mathrm{NO}_{x} \rightarrow \mathrm{HNO}_{3}$
with $\mathrm{d}\left[\mathrm{HNO}_{3}\right] / \mathrm{dt}=-\mathrm{d}\left[\mathrm{NO}_{\mathrm{x}}\right] / \mathrm{dt}=k_{6}\left[\mathrm{NO}_{\mathrm{x}}\right]$, and $k_{6}=1 \mathrm{~d}^{-1}$.
3.1 The mass balance equation for $\mathrm{NO}_{\mathrm{x}}$ is

$$
-\frac{d\left[N O_{x}\right]}{d t}=-k_{6}\left[N O_{x}\right]
$$

Integration yields:

$$
\left[N O_{x}\right]=\left[N O_{x}\right]_{0} e^{-k_{6} t}
$$

with the initial condition $\left[\mathrm{NO}_{\mathrm{x}}\right]_{\mathrm{O}}=100 \mathrm{ppbv}$ at time $t=0$. After 10 days, $\left[\mathrm{NO}_{\mathrm{x}}\right]=100 \mathrm{e}^{-10}=4.5 \times 10^{-3} \mathrm{ppbv}=4.5 \mathrm{pptv}$ (small!).
3.2.1. Accounting for PAN formation, the lifetime of $\mathrm{NO}_{\mathrm{x}}$ is given by:

$$
\tau_{\mathrm{NO}_{x}}=\frac{1}{k_{6}+k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right] \frac{\left[\mathrm{NO}_{2}\right]}{\left[\mathrm{NO}_{x}\right]}} \approx \frac{1}{k_{6}+k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]}
$$

where we have made use of the approximation $[\mathrm{NO}] \ll\left\{\mathrm{NO}_{2}\right] \Rightarrow\left[\mathrm{NO}_{2}\right] /\left[\mathrm{NO}_{\mathrm{x}}\right] \approx 1$. Replacing numerical values we obtain $\tau_{\mathrm{NOx}}=35$ minutes; loss of $\mathrm{NO}_{\mathrm{x}}$ is dominated by conversion to PAN.
The lifetime of PAN is $\tau_{\text {PAN }}=1 / k_{5}$. At $298 \mathrm{~K}, k_{5}=3.6 \times 10^{-4} \mathrm{~s}^{-1}$ and $\tau_{\text {PAN }}=47$ minutes; at $260 \mathrm{~K}, k_{5}=$ $4.6 \times 10^{-7} \mathrm{~s}^{-1}$ and $\tau_{\text {PAN }}=25$ days.
3.2.2. Formation of PAN leads to a chemical source of $\mathrm{NO}_{\mathrm{x}}$ in the air parcel by the reverse reaction (5). Considering that the lifetime of $\mathrm{NO}_{\mathrm{x}}\left(\tau_{\mathrm{NOx}}=35\right.$ minutes $)$ is short relative to the 10 -day integration time, we can assume quasi steady state for $\mathrm{NO}_{\mathrm{x}}$ :

$$
k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]\left[\mathrm{NO}_{x}\right]+k_{6}\left[\mathrm{NO}_{x}\right]=k_{5}[\mathrm{PAN}]
$$

so that

$$
[P A N]=\frac{k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]\left[\mathrm{NO}_{x}\right]}{k_{5}}
$$

where we have made the approximations $\left[\mathrm{NO}_{2}\right] /\left[\mathrm{NO}_{x}\right] \approx 1$ and $k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right] \gg k_{6}$. Let us define the chemical family $\mathrm{NO}_{\mathrm{x}}{ }^{*}=\mathrm{NO}_{\mathrm{x}}+\mathrm{PAN}$; from the above equation, we derive

$$
\left[\mathrm{NO}_{x}\right]=\frac{\left[\mathrm{NO}_{x}^{*}\right]}{1+\frac{k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]}{k_{5}}}
$$

Replacing numerical values, we find that the initial $100 \mathrm{ppbv} \mathrm{NO}_{\mathrm{x}}{ }^{*}$ in the air parcel at time $t=0$ quickly partition into $43 \mathrm{ppbv} \mathrm{NO}_{x}$ and 57 ppbv PAN; further temporal evolution of $\mathrm{NO}_{x}$ and PAN over the 10day period is governed by slow conversion of $\mathrm{NO}_{x}$ to $\mathrm{HNO}_{3}$. Consider the mass balance equation for $\mathrm{NO}_{\mathrm{x}}{ }^{*}$, for which the only loss is reaction (6):

$$
\frac{d\left[N O_{x}^{*}\right]}{d t}=-k_{6}\left[N O_{x}\right]
$$

Replace in this equation the above quasi steady-state equation for $\left[\mathrm{NO}_{\mathrm{x}}\right]$ :

$$
\left(1+\frac{k_{4 b}\left[\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}\right]}{k_{5}}\right) \frac{d\left[\mathrm{NO}_{x}\right]}{d t}=-k_{6}\left[\mathrm{NO}_{x}\right]
$$

so that

$$
\frac{d\left[\mathrm{NO}_{x}\right]}{d t}=-\frac{k_{6}}{1+\frac{k_{4 b} C H_{3} \mathrm{COOO}}{k_{5}}}\left[\mathrm{NO}_{x}\right]
$$

Thus the temporal evolution of the $\mathrm{NO}_{\mathrm{x}}$ concentration is given by:

$$
\left[N O_{x}\right]=\left[N O_{x}\right]_{0} e^{-\frac{t}{\tau_{N O x}^{*}}}
$$

where $\left[\mathrm{NO}_{\mathrm{x}}\right]_{\mathrm{o}}=43 \mathrm{ppbv}$ (the initial concentration following equilibration with PAN) and where

$$
\tau_{\mathrm{NOx}}^{*}=\frac{1+\frac{k_{4 b} \mathrm{CH}_{3} \mathrm{COOO}}{k_{5}}}{k_{6}}
$$

is an effective lifetime for $\mathrm{NO}_{\mathrm{x}}$. Inserting numerical values we obtain $\tau^{*}{ }_{\mathrm{NOx}}=2.3$ days. Compared to the atmosphere without PAN formation, where the lifetime of $\mathrm{NO}_{\mathrm{x}}$ was $\tau_{\mathrm{NOx}}=1 / k_{6}=1$ day, the formation of PAN initially decreased the $\mathrm{NO}_{\mathrm{x}}$ concentration from 100 ppbv to 43 ppbv but then subsequently increased the effective lifetime of $\mathrm{NO}_{\mathrm{x}}$ by a factor 2.3. After 10 days, $\left[\mathrm{NO}_{\mathrm{x}}\right]=43 \mathrm{e}^{-10 / 2.3}=0.56 \mathrm{ppbv}$. This is two orders of magnitude higher than the value calculated in question 3.1, ignoring PAN formation!
3.2.3. The same equations apply to 260 K (we can still assume quasi steady state for $\mathrm{NO}_{\mathrm{x}}$ ) but now $k_{5}$ is much lower. Replacing numerical values we find that the initial partitioning of $\mathrm{NO}_{\mathrm{x}}{ }^{*}$ between $\mathrm{NO}_{\mathrm{x}}$ and PAN yields $0.10 \mathrm{ppbv} \mathrm{NO}_{\mathrm{x}}$ and 99.9 ppbv PAN. The effective lifetime of $\mathrm{NO}_{\mathrm{x}}$ is $\tau^{*} \mathrm{NO}_{\mathrm{x}}=2.8$ years! Thus $\mathrm{NO}_{\mathrm{x}}$ remains constant at 0.10 ppbv over the 10-day period, less than in the previous calculation but still much more than in the calculation without PAN formation. When the temperature eventually rises, PAN will decompose and $\mathrm{NO}_{\mathrm{x}}$ will increase.
3.2.4 We saw in this problem the importance of PAN formation in facilitating the long-range transport of $\mathrm{NO}_{\mathrm{x}}$ in the atmosphere, both at warm and cold temperatures. At warm temperatures, formation of PAN increases the effective lifetime of $\mathrm{NO}_{x}$. At cold temperatures, formation of PAN maintains a background $\mathrm{NO}_{\mathrm{x}}$ concentration and provides a reservoir to eventually deliver $\mathrm{NO}_{\mathrm{x}}$ to the atmosphere when the temperature rises.

## 11. 10 Photochemical equilibrium of $\mathrm{NO}_{x}$ and $\mathrm{HNO}_{3}$

1. The lifetime of $\mathrm{NO}_{\mathrm{x}}$ is
$\tau_{\mathrm{NO} x}=\frac{\left[\mathrm{NO}_{x}\right]}{k_{3}\left[\mathrm{NO}_{2}\right][\mathrm{OH}]}=\frac{\frac{[\mathrm{NO}]}{\left[\mathrm{NO}_{2}\right]}+1}{k_{3}[\mathrm{OH}]}$
Assuming chemical steady state for NO, and using the approximation rate(2)>>rate(3):

$$
k_{1}[N O]\left[O_{3}\right]=k_{2}\left[N O_{2}\right]
$$

Replacing in the expression for the $\mathrm{NO}_{\mathrm{x}}$ lifetime:
$\tau_{N O x}=\frac{\frac{[N O]}{\left[\mathrm{NO}_{2}\right]}+1}{k_{3}[\mathrm{OH}]}=\frac{\frac{k_{2}}{k_{1}\left[O_{3}\right]}+1}{k_{3}[O H]}$

The lifetime of $\mathrm{HNO}_{3}$ is given by
$\tau_{\mathrm{HNO} 3}=\frac{1}{k_{4}[\mathrm{OH}]+k_{5}}$
At $2 \mathrm{~km}(T=287 \mathrm{~K}), \tau_{\mathrm{NOx}}=1.3$ days and $\tau_{\mathrm{HNO}}=23$ days
At $10 \mathrm{~km}(T=235 \mathrm{~K}), \tau_{\mathrm{NOx}}=6.6$ days and $\tau_{\mathrm{HNO}}=19$ days
The opposite dependences of $\tau_{\mathrm{NOx}}$ and $\tau_{\mathrm{HNO}}$ on altitude reflect the opposite Arrhenius temperature dependences of reaction (1) and reaction (4)
2. Steady state for $\mathrm{NO}_{\mathrm{x}}$ is defined by a balance between the production rate $\left[\mathrm{HNO}_{3}\right] / \tau_{\mathrm{HNO}}$ and the loss rate $\left[\mathrm{NO}_{\mathrm{x}}\right] / \tau_{\mathrm{NOx}}$. Therefore
$\frac{\left[\mathrm{HNO}_{3}\right]}{\left[\mathrm{NO}_{x}\right]}=\frac{\tau_{\mathrm{NOx}}}{\tau_{\mathrm{HNO} 3}}$
3. The mass balance equation for $\mathrm{NO}_{\mathrm{x}}$ in the air parcel, following the initial injection, is

$$
\frac{d\left[\mathrm{NO}_{x}\right]}{d t}=\frac{\left[H N O_{3}\right]}{\tau_{\mathrm{HNO}}}-\frac{\left[N O_{x}\right]}{\tau_{\mathrm{NOX}}}
$$

Since $\mathrm{NO}_{x}$ and $\mathrm{HNO}_{3}$ are conserved in the air parcel, $\left[\mathrm{HNO}_{3}\right]=\left[\mathrm{NO}_{x}\right]_{0}-\left[\mathrm{NO}_{x}\right]$. Substituting in the above equation,

$$
\frac{d\left[N O_{x}\right]}{d t}=\frac{\left[N O_{x}\right]_{o}}{\tau_{H N O 3}}-\left(\frac{1}{\tau_{N O x}}+\frac{1}{\tau_{H N O 3}}\right)\left[N O_{x}\right]
$$

which is of the form
$\frac{d\left[N O_{x}\right]}{d t}=P-k\left[N O_{x}\right]$
where $P=\left[\mathrm{NO}_{\mathrm{x}}\right]_{\mathrm{o}} / \tau_{\mathrm{HNO} 3}$ and $k=\left(1 / \tau_{\mathrm{NOx}}+1 / \tau_{\mathrm{HNO} 3}\right)$. The solution to this equation is
$\left[N O_{x}\right]=\left[N O_{x}\right]_{0} e^{-k t}+\frac{P}{k}\left(1-e^{-k t}\right)$
so that $\left[\mathrm{NO}_{\mathrm{x}}\right]$ approaches steady state on a time scale $\tau=1 / k=\left(1 / \tau_{\mathrm{NOx}}+1 / \tau_{\mathrm{HNO}}\right)^{-1}$. Since $\left[\mathrm{HNO}_{3}\right]=$ $\left[\mathrm{NO}_{\mathrm{x}}\right]_{0}-\left[\mathrm{NO}_{\mathrm{x}}\right],\left[\mathrm{HNO}_{3}\right]$ approaches steady state on the same time scale. This is the desired result.

At $2 \mathrm{~km}, \tau=(1 / 1.3)+(1 / 23)=1.2$ days
At $10 \mathrm{~km}, \tau=(1 / 6.6)+(1 / 19)=4.9$ days
The time scale over which the $\mathrm{HNO}_{3} / \mathrm{NO}_{x}$ concentration ratio approaches chemical steady state is shorter than the lifetime of the shortest species $\left(\mathrm{NO}_{\mathrm{x}}\right)$. It is sufficiently short that one would in general expect to be close to chemical steady state.
4. The chemical steady state value of the $\mathrm{HNO}_{3} / \mathrm{NO}_{x}$ concentration ratio increases rapidly with altitude, from $1.3 / 23=0.06 \mathrm{~mol} / \mathrm{mol}$ at 2 km to $6.6 / 19=0.35 \mathrm{~mol} / \mathrm{mol}$ at 10 km . As an air parcel initially at chemical steady state subsides, its $\mathrm{HNO}_{3} / \mathrm{NO}_{x}$ concentration ratio will always be higher than the local chemical steady state value. Depending on the rate of subsidence, the departure from steady state may be large. As an extreme case, an air parcel brought down instantly from 10 km to 2 km would have a $\mathrm{HNO}_{3} / \mathrm{NO}_{\mathrm{x}}$ concentration ratio $0.35 / 0.06=6$ times higher than local chemical steady state.
5. Injection of fresh $\mathrm{NO}_{x}$ to the upper troposphere could take place by deep convection, lightning, or aircraft.

## SOLUTIONS TO PROBLEMS, CHAPTER 12

## 12. $1 \mathrm{NO}_{x}$ - and hydrocarbon-limited regimes for ozone production

1. The loss rate of $\mathrm{NO}_{\mathrm{x}}$ from oxidation in the region is

$$
L_{N O x}=\frac{\left[N O_{x}\right]}{\tau_{N O x}}
$$

and the loss rate of $\mathrm{NO}_{x}$ from ventilation out of the region is

$$
F_{N O x}=\frac{U\left[N O_{x}\right]}{W}
$$

where $\left[\mathrm{NO}_{\mathrm{x}}\right]$ is the $\mathrm{NO}_{\mathrm{x}}$ concentration in the region, $\tau_{\mathrm{NOx}}=12$ hours is the lifetime of $\mathrm{NO}_{\mathrm{x}}$ against oxidation, $U=2 \mathrm{~m} \mathrm{~s}^{-1}$ is the wind speed from the west, and $W=1000 \mathrm{~km}$ is the east-west dimension of the region. The fraction $f$ of the $\mathrm{NO}_{\mathrm{x}}$ removed by oxidation is

$$
f=\frac{L_{N O x}}{L_{N O x}+F_{N O x}}=\frac{1}{1+\frac{\tau_{N O x} U}{W}}=0.92
$$

Indeed most of the $\mathrm{NO}_{\mathrm{x}}$ is oxidized withn the region.
2. We must express the source of $\mathrm{HO}_{\mathrm{x}}, P_{H O x}=4 \times 10^{6}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}$, and the emission of $\mathrm{NO}_{\mathrm{x}}, E_{N O x}=$ $2 \times 10^{11}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$, in the same units. Let us convert $E_{N O x}$ into a mean source of $\mathrm{NO}_{\mathrm{x}}, P_{\text {NOx }}$, in the eastern United States box:
$P_{N O x}=E_{\text {NOx }}($ area $/$ volume $)=E_{N O x} / h$
where $h=2 \mathrm{~km}$ is the height of the box. Thus $P_{N O x}=1 \times 10^{6}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}<P_{H O x}=4 \times 10^{6}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}$.

Steady state for $\mathrm{HO}_{\mathrm{x}}$ is defined by:
$P_{H O x}=L_{H O x}(1)+L_{\text {HOx }}(2)=L_{\text {HOx }}(1)+f P_{\text {NOx }}$
where $L_{H O x}(1)$ and $L_{H O x}(2)$ are the loss rates of $\mathrm{HO}_{x}$ by reactions (1) and (2), respectively; $L_{H O x}(1)>$ $L_{H O x}(2)$ defines the $\mathrm{NO}_{x}$-limited regime. Rearranging the above equation,
$L_{H O x}(1)=P_{H O x}-f P_{\text {NOX }}=4 \times 10^{6}-9 \times 10^{5}=3.1 \times 10^{6}$ molecules $\mathrm{cm}^{-3} \mathrm{~s}^{-1}>L_{H O x}$ (2)
We conclude that $\mathrm{O}_{3}$ production is $\mathrm{NO}_{x}$-limited.
3.1. $P_{H O x}$ is less in October than in July because of the weaker radiation available for photolysis of $\mathrm{O}_{3}$, which provides the principal source of $\mathrm{HO}_{x}$.
3.2. In October $P_{H O x} \approx f P_{N O x}$; the source of $\mathrm{HO}_{\mathrm{x}}$ is sufficiently weak that reaction (2) can provide the main sink of $\mathrm{HO}_{x}$. Thus $L_{H O x}(2)>L_{H O x}(1)$ and $\mathrm{O}_{3}$ production is hydrocarbon-limited.
4. Schematic for $\mathrm{HO}_{\mathrm{x}}$ cycling:

4.1. Ozone production rate $P_{\mathrm{O} 3}=\operatorname{rate}(5)+\operatorname{rate}(7)$

Assume efficient cycling between $\mathrm{HO}_{x}$ species so that rate(5)=rate(7) and therefore $P_{O 3}=2 \operatorname{rate}(5)=$ $2 k_{5}\left[\mathrm{RO}_{2}\right][\mathrm{NO}]$.

Use steady-state for $\mathrm{HO}_{x}$ to substitute for $\mathrm{RO}_{2}$ :
$\mathrm{P}_{\mathrm{HOx}}=\mathrm{L}_{\mathrm{HOx}} \approx \mathrm{k}_{3}\left[\mathrm{RO}_{2}\right]\left[\mathrm{NO}_{2}\right][\mathrm{M}]$
since we assume that reaction (3) is the dominant loss process for $\mathrm{HO}_{\mathrm{x}}$. Replacing in above equation:

$$
P_{O_{3}}=2 k_{5}\left(\frac{P_{\mathrm{HOx}}}{k_{3}\left[\mathrm{NO}_{2}\right][\mathrm{M}]}\right)[\mathrm{NO}]
$$

4.2. If $[\mathrm{NO}] /\left[\mathrm{NO}_{2}\right]$ is constant, $\mathrm{P}_{\mathrm{O} 3}$ is only a function of $P_{\mathrm{HOx}}$ which depends on $\mathrm{O}_{3}, h \nu$, and $\mathrm{H}_{2} \mathrm{O}$. Ozone production does not depend directly on either $\mathrm{NO}_{\mathrm{x}}$ or hydrocarbons.

## 12. 2 Ozone titration in a fresh plume

1. Consider an elemental section of plume of thickness $d x$ at a distance $x$ from the source; the crosssectional area of the plume is $A=\pi R^{2} / 2=\alpha^{2} \pi x^{2} / 2$ and its volume is $A d x$. Considering that $\mathrm{NO}_{\mathrm{x}}$ is conserved in the plume and that air resides in the elemental section of plume for a time $d t=d x / U$, the
number of moles of $\mathrm{NO}_{\mathrm{x}}$ in the elemental section is $Q d t=Q d x / U$. The concentration of $\mathrm{NO}_{\mathrm{x}}$ is
$\left[\mathrm{NO}_{\mathrm{x}}\right](x)=\left(\#\right.$ moles $\left.\mathrm{NO}_{\mathrm{x}}\right) /$ volume $=2 \mathrm{Q} /\left(\alpha^{2} \pi x^{2} U\right)$ in units of moles $\mathrm{m}^{-3}$
$\left[\mathrm{NO}_{\mathrm{x}}\right](x)=2 \mathrm{Q} /\left(\alpha^{2} \pi x^{2} U \beta\right)$ in units of ppb .
2. If there were no ozone entrained in the plume, then all of the NO would remain NO as the plume advected downwind. The only process by which NO is converted to $\mathrm{NO}_{2}$ is by reaction 1. As such, the concentration of ozone is the background concentration minus the amount destroyed in production of $\mathrm{NO}_{2}$, the latter term being equivalent to eh concentration of $\mathrm{NO}_{2}$ produced in the plume:

$$
\left[O_{3}\right](x)=\left[O_{3}\right] b-\left[N O_{2}\right](x)
$$

3. 

$$
\begin{gather*}
{\left[O_{3}\right](x)=\left[O_{3}\right] b-\left[N O_{2}\right](x)}  \tag{1}\\
{\left[N O_{2}\right](x)+[N O](x)=\frac{2 Q}{\pi \beta \alpha^{2} x^{2} U}}  \tag{2}\\
K=\frac{[N O](x)\left[O_{3}\right](x)}{\left[N O_{2}\right](x)}
\end{gather*}
$$

Substitute eq. 3 into eq. 2:

$$
\left[N O_{2}\right](x)+\frac{K\left(\left[N O_{2}\right](x)\right)}{\left[O_{3}\right](x)}=\frac{2 Q}{\pi \beta \alpha^{2} x^{2} U}
$$

Solve this for $\left[\mathrm{NO}_{2}\right](x)$ and replace into eq. 1.

$$
\left[O_{3}\right](x)=\left[O_{3}\right] b-\frac{\frac{2 Q}{\pi U \beta \alpha^{2} x^{2}}}{\left(1+\frac{K}{\left[O_{3}\right](x)}\right)}
$$

Solve this for $\left[\mathrm{O}_{3}\right](\mathrm{x})$ :

$$
\begin{gathered}
{\left[O_{3}\right]^{2}(x)+\left[O_{3}\right](x)\left(K+\frac{2 Q}{U \pi \beta \alpha^{2} x^{2}}-\left[O_{3}\right] b\right)-K\left(\left[O_{3}\right] b\right)=0} \\
{\left[O_{3}\right](x)=\frac{-\left(K+\frac{2 Q}{U \pi \beta \alpha^{2} x^{2}}-\left[O_{3}\right] b\right)+\sqrt{\left(K+\frac{2 Q}{U \pi \beta \alpha^{2} x^{2}}-\left[O_{3}\right] b\right)^{2}+4 K\left(\left[O_{3}\right] b\right)}}{2}}
\end{gathered}
$$

Plot the result:

The ozone concentration in the plume recovers to $90 \%$ of background levels (i.e., 45 ppbv ) at 30 km downwind of the source.

## SOLUTIONS TO PROBLEMS, CHAPTER 13

## 13. 1 Anthropogenic emissions and acid rain

1. The United States receives $1.3 \times 10^{9}$ moles per day of $\mathrm{H}^{+}$as $\mathrm{HNO}_{3}$ from $\mathrm{NO}_{\mathrm{x}}$ emissions and $2 \times 10^{9}$ moles per day of $\mathrm{H}^{+}$as $\mathrm{H}_{2} \mathrm{SO}_{4}$ from $\mathrm{SO}_{2}$ emissions $\left(\mathrm{H}_{2} \mathrm{SO}_{4}\right.$ releases two $\left.\mathrm{H}^{+}\right)$. This totals $N=3.3 \times 10^{9}$ moles per day of $\mathrm{H}^{+}$. We divide by the total volume $V$ of water precipitating per day over the United States:
$V=1 \times 10^{7}\left(\mathrm{~km}^{2}\right) \times 2\left(\mathrm{~mm}\right.$ day $\left.^{-1}\right)=2 \times 10^{13}$ liters day $^{-1}$
The mean $\mathrm{H}^{+}$concentration is therefore $\left[\mathrm{H}^{+}\right]=N / V=3.3 \times 10^{9} / 2 \times 10^{13}=1.7 \times 10^{-4} \mathrm{M}$ and the corresponding pH is 3.8 .

To get the concentration of $\mathrm{H}^{+}$we need to divide the latter figure by the total volume of water:

$$
2 \times 10^{-6}\left(\frac{\mathrm{~km}}{\mathrm{day}}\right) 1 \times 10^{7} \mathrm{~km}^{2}=2 \frac{\mathrm{~km}^{3}}{d a y}=2 \times 10^{13} \frac{\mathrm{~L}}{d a y}
$$

2. The actual pH range is 4.2 to 5.5 ; our simple calculation in question 1 overestimates $\left[\mathrm{H}^{+}\right]$because it does not take into account the presence of bases such as $\mathrm{NH}_{3}$ and $\mathrm{CaCO}_{3}$ which scavenge $\mathrm{H}^{+}$.

## 13. 2 The true acidity of rain

Consider the electroneutrality equation for a rain sample analyzed in the lab :

$$
\Sigma\left[\mathrm{Cat}^{+}\right]_{l a b}+\left[\mathrm{H}^{+}\right]_{l a b}=\Sigma\left[A n^{-}\right]_{l a b}
$$

where $\Sigma\left[\mathrm{Cat}^{+}\right]$is the sum of concentrations of cations other than $\mathrm{H}^{+}, \Sigma\left[\mathrm{An}^{-}\right]$is the sum of concentrations of anions, and $[\mathrm{H}]_{\text {lab }}$ corresponds to the pH of the sample measured in the lab: $\mathrm{pH}=4.7$, therefore $\left[\mathrm{H}^{+}\right]_{\text {lab }}$ $=2.0 \times 10^{-5} \mathrm{M} . \mathrm{HCOOH}$ present originally in the rain has been consumed prior to analysis; we assume that all other cations ( $\mathrm{Cat}^{+}$) and anions ( $\mathrm{An}^{-}$) have been preserved. The true electroneutrality for the actual rain sample before HCOOH has decayed is

$$
\begin{gathered}
\Sigma\left[\mathrm{Cat}^{+}\right]_{\text {lab }}+\left[\mathrm{H}^{+}\right]_{\text {true }}=\Sigma\left[\mathrm{An}^{-}\right]_{l a b}+\left[\mathrm{HCOO}^{-}\right] \\
\Rightarrow\left[\mathrm{H}^{+}\right]_{\text {true }}=\left[\mathrm{H}^{+}\right]_{\text {lab }}+\left[\mathrm{HCOO}^{-}\right] \\
\Rightarrow\left[\mathrm{H}^{+}\right]_{\text {true }}=\left[\mathrm{H}^{+}\right]_{\text {lab }}+\frac{\mathrm{K}_{H} K_{1} P_{\mathrm{HCOOH}}}{\left[\mathrm{H}^{+}\right]_{\text {true }}} \\
\Rightarrow\left[\mathrm{H}^{+}\right]_{\text {true }}^{2}-\left[\mathrm{H}^{+}\right]_{\text {lab }}\left[\mathrm{H}^{+}\right]_{\text {true }}-K_{H} K_{1} P_{\mathrm{HCOOH}}=0
\end{gathered}
$$

Solution to this quadratic equation yields $\left[\mathrm{H}^{+}\right]_{\text {true }}=3.8 \times 10^{-5} \mathrm{M}$, or a true pH of 4.4. We find that HCOOH accounts here for almost half of total rain acidity! However, it does no harm to ecosystems because it is rapidly consumed by microbes. From the perspective of damage to ecosystems, there is some rationale for measuring pH after HCOOH has decayed.

## 13. 3 Aqueous-phase oxidation of $\mathrm{SO}_{2}$ by ozone

1. Reaction (1) consumes $\mathrm{SO}_{3}{ }^{2-}$, thereby shifting equilibria (4) and (3) to the right and releasing $\mathrm{H}^{+}$.
2. Calculate the rate of sulfate production by reaction (1):

$$
\begin{gathered}
\frac{d\left[\mathrm{SO}_{4}^{2-}\right]}{d t}=k_{1}\left[\mathrm{SO}_{3}^{2-}\right]\left[\mathrm{O}_{3}(\mathrm{aq})\right] \\
=k_{1} \frac{K_{2} K_{3} K_{4} P_{S O 2}}{\left[H^{+}\right]^{2}} K_{5} P_{O 3}
\end{gathered}
$$

Substituting numerical values, we find $d\left[\mathrm{SO}_{4}{ }^{2-}\right] / d t=5.4 \times 10^{-9} \mathrm{M} \mathrm{s}^{-1}$ or $4.7 \times 10^{-4} \mathrm{M}$ day ${ }^{-1}$ at pH 5 , and 100 times less at pH 4 . Starting from $\left[\mathrm{H}^{+}\right]=1 \times 10^{-5} \mathrm{M}$ at pH 5 , significant acidity could be produced from the reaction over a time scale of several hours. However, the rate of acid production would decrease rapidly as $\left[\mathrm{H}^{+}\right]$increases, and is negligibly small at pH 4.
[

## 13. 4 The acid fog problem

1.Steady state for $\mathrm{SO}_{2}$ :

$$
\frac{E}{h}=\left(k_{d}+k_{o}\right)\left[\mathrm{SO}_{2}\right]
$$

where $h=400 \mathrm{~m}$ is the mixing depth (height of the box); $E / h$ is the source of $\mathrm{SO}_{2}$ per unit volume. Rearranging:

$$
\left[\mathrm{SO}_{2}\right]=\frac{E}{h\left(k_{d}+k_{o}\right)} \text { (number density)"" }=\frac{E}{h\left(k_{d}+k_{o}\right)} \frac{P}{R T} \text { (mixing ratio) }
$$

Replacing numerical values yields $\left[\mathrm{SO}_{2}\right]=15 \mathrm{ppbv}$.
This level of pollution is below the EPA standards.
2. Since $\mathrm{H}_{2} \mathrm{SO}_{4}$ is incorporated immediately in the fog droplets, it is removed from the atmosphere at the same rate constant as the fog droplets. Steady state for $\mathrm{H}_{2} \mathrm{SO}_{4}$ :

$$
k_{o}\left[\mathrm{SO}_{2}\right]=k_{d}^{\prime}\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]
$$

Each $\mathrm{H}_{2} \mathrm{SO}_{4}$ molecule dissociates in the fog droplets to yield two $\mathrm{H}^{+}$ions, so that the concentration $\left[\mathrm{H}^{+}\right]$ in the fogwater (liquid water content $L$ ) is

$$
\left[\mathrm{H}^{+}\right]=\frac{2\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]}{L}=\frac{2 k_{o}\left[\mathrm{SO}_{2}\right]}{k_{d}^{\prime} L}
$$

which gives a fogwater pH of 2.18 .
3. $\mathrm{NH}_{3}$ reacts to consume $\mathrm{H}^{+}$in a 1:1 stochiometric ratio:

$$
\mathrm{NH}_{3}+\mathrm{H}^{+} \rightarrow \mathrm{NH}_{4}^{+}
$$

The source $P_{\mathrm{H}+}$ of $\mathrm{H}^{+}$in the valley (in moles $\mathrm{km}^{-2}$ day ${ }^{-1}$ ) is given by the emission of $\mathrm{SO}_{2}\left(E_{\mathrm{SO} 2}\right)$ times the fraction of that $\mathrm{SO}_{2}$ that is oxidized to $\mathrm{H}_{2} \mathrm{SO}_{4}\left(k_{0} /\left(k_{0}+k_{d}\right)\right)$ times two (since each $\mathrm{H}_{2} \mathrm{SO}_{4}$ molecule releases two $\mathrm{H}^{+}$ions). We obtain $P_{H^{+}}=4 \times 10^{12} \times(1 / 1.5) \times 2=5.3 \times 10^{12}$ moles $\mathrm{km}^{-2}$ day $^{-1}$. There is just enough $\mathrm{NH}_{3}$ emitted to neutralize this acidity.

## 13. 5 Acid rain: the pre-industrial atmosphere

1. Calculate the pH of rain at equilibrium with $P_{\mathrm{CO} 2}=280 \mathrm{ppmv}$. The relevant equilibrium relationships are:

$$
\begin{aligned}
& K_{1}=\frac{\left[\mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}\right]}{P_{\mathrm{CO} 2}} \\
& K_{2}=\frac{\left[\mathrm{HCO}_{3}^{-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}\right]}
\end{aligned}
$$

We also consider the charge balance equation:

$$
\left[\mathrm{H}^{+}\right]=\left[\mathrm{HCO}_{3}^{-}\right]+\left[\mathrm{OH}^{-}\right]
$$

Since $\mathrm{CO}_{2}$ is a weak acid, we can assume $\left[\mathrm{H}^{+}\right] \gg\left[\mathrm{OH}^{-}\right]$and simplify the charge balance equation (this assumption will be verified at the end):

$$
\left[\mathrm{H}^{+}\right]=\left[\mathrm{HCO}_{3}^{-}\right]
$$

We thus have three equations for the three unknowns $\left[\mathrm{H}^{+}\right],\left[\mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}\right],\left[\mathrm{HCO}_{3}^{-}\right]$; this leads to a unique solution for $\left[\mathrm{H}^{+}\right]$which we obtain by substitution:

$$
\left[H^{+}\right]=\left(K_{1} K_{2} P_{\mathrm{CO} 2}\right)^{\frac{1}{2}}
$$

Replacing numerical values yields $\left[\mathrm{H}^{+}\right]=2.1 \times 10^{-6} \mathrm{M}$, or $\mathrm{pH}=5.7$. The assumption $\left[\mathrm{H}^{+}\right] \gg\left[\mathrm{OH}^{-}\right]$is verified.
2. Including the organic acids with $P_{\mathrm{HCOOH}}=0.1 \mathrm{ppbv}$ and $P_{\mathrm{CH} 3 \mathrm{COOH}}=0.1 \mathrm{ppbv}$ adds the equilibrium relationships:

$$
\begin{aligned}
K_{3} K_{4} & =\frac{\left[\mathrm{HCOO}^{-}\right]\left[\mathrm{H}^{+}\right]}{P_{\mathrm{HCOOH}}} \\
K_{5} K_{6} & =\frac{\left[\mathrm{CH}_{3} \mathrm{COO}^{-}\right]\left[\mathrm{H}^{+}\right]}{P_{\mathrm{CH} 3 \mathrm{COOH}}}
\end{aligned}
$$

and the charge balance equation is now:

$$
\left[\mathrm{H}^{+}\right]=\left[\mathrm{HCO}_{3}^{-}\right]+\left[\mathrm{HCOO}^{-}\right]+\left[\mathrm{CH}_{3} \mathrm{COO}^{-}\right]
$$

Replacing the equilibrium relationships into the charge balance equation we obtain

$$
\left[H^{+}\right]=\left(K_{1} K_{2} P_{\mathrm{CO} 2}+K_{3} K_{4} P_{\mathrm{HCOOH}}+K_{5} K_{6} P_{\mathrm{CH} 3 \mathrm{COOH}}\right)^{\frac{1}{2}}
$$

Replacing numerical values for the individual terms on the right-hand side:

$$
\left[H^{+}\right]=\left(4.6 \times 10^{-12}+6.7 \times 10^{-11}+1.5 \times 10^{-11}\right)^{\frac{1}{2}}
$$

we obtain $\left[\mathrm{H}^{+}\right]=9.3 \times 10^{-6} \mathrm{M}$, or $\mathrm{pH}=5.0$. Most of the acidity is contributed by formic acid ( HCOOH ).
3.1 The surface area of Earth $=4 \pi\left(6400 \times 10^{5} \mathrm{~cm}\right)^{2}=5.1 \times 10^{18} \mathrm{~cm}^{2}$; so a global mean precipitation rate of 0.2 cm day $^{-1}$ corresponds to $3.7 \times 10^{17}$ liters $\mathrm{yr}^{-1}$.

$$
\begin{aligned}
& {\left[\mathrm{NO}_{3}^{-}\right]=1 \times 10^{12} \text { moles } \mathrm{yr}^{-1} / 3.7 \times 10^{17} \text { liters } \mathrm{yr}^{-1}=2.7 \times 10^{-6} \text { moles } / \text { liter }} \\
& {\left[\mathrm{SO}_{4}^{2-}\right]=1 \times 10^{12} \text { moles } \mathrm{yr}^{-1} / 3.7 \times 10^{17} \text { liters } \mathrm{yr}^{-1}=2.7 \times 10^{-6} \mathrm{moles} / \text { liter }}
\end{aligned}
$$

3.2 The charge balance equation is now

$$
\left[\mathrm{H}^{+}\right]=\left[\mathrm{HCO}_{3}^{-}\right]+\left[\mathrm{HCOO}^{-}\right]+\left[\mathrm{CH}_{3} \mathrm{COO}^{-}\right]+\left[\mathrm{NO}_{3}^{-}\right]+2\left[\mathrm{SO}_{4}^{2-}\right]
$$

Substitution yields a 2nd-degree equation for $\left[\mathrm{H}^{+}\right]$:
$\left[\mathrm{H}^{+}\right]^{2}-\left(\left[\mathrm{NO}_{3}^{-}\right]+2\left[\mathrm{SO}_{4}^{2-}\right]\right)\left[\mathrm{H}^{+}\right]-\left(\mathrm{K}_{1} \mathrm{~K}_{2} \mathrm{P}_{\mathrm{CO} 2}+\mathrm{K}_{3} \mathrm{~K}_{4} P_{\mathrm{HCOOH}}+\mathrm{K}_{5} \mathrm{~K}_{6} P_{\mathrm{CH} 3 \mathrm{COOH}}\right)=0$
Replacing numerical values:

$$
\left[H^{+}\right]^{2}-8.1 \times 10^{-6}\left[H^{+}\right]-8.7 \times 10^{-11}=0
$$

we obtain $\left[\mathrm{H}^{+}\right]=1.4 \times 10^{-5} \mathrm{M}$, or $\mathrm{pH}=4.85$. At that pH ,

$$
\left[\mathrm{HCOO}^{-}\right]=\frac{\mathrm{K}_{3} \mathrm{~K}_{4} P_{\mathrm{HCOOH}}}{\left[\mathrm{H}^{+}\right]}=4.8 \times 10^{-6} \mathrm{M}
$$

and hence $\left[\mathrm{HCOO}^{-}\right]<2\left[\mathrm{SO}_{4}{ }^{2-}\right]$. Thus $\mathrm{H}_{2} \mathrm{SO}_{4}$ was the most important acid in the preindustrial atmosphere, followed closely by HCOOH .
